a_{hm}	=	cross-sectional area of horizontal reinforcement per unit width at midspan of facing (in. ² /ft) (11.12.6.2.2)
a_{hn}	=	cross-sectional area of horizontal reinforcement per unit width at nail head (in. ² /ft) (11.12.6.2.2)
a_{vm}	=	cross-sectional area of vertical reinforcement per unit width at midspan of facing (in. ² /ft) (11.12.6.2.2)
a_{vn}	=	cross-sectional area of vertical reinforcement per unit width at nail head (in. ² /ft) (11.12.6.2.2)

B	=	wall base width (ft) (11.10.2)
b	=	unit width of reinforcement; width of bin module (ft) (11.10.6.4.1) (11.11.5.1)
b_f	=	width of applied footing load (ft) (11.10.10.2)
C	=	overall reinforcement surface area geometry factor (dim.) (11.10.6.3.2)
C_F	=	factor to consider nonuniform soil pressures behind soil nail wall facing (dim.) (11.12.6.2.2)
C_h	=	coefficient used to determine z_b and D_{tmax} (dim.) (11.10.6.2.1e)
C_P	=	correction factor to account for contribution of soil support in punching shear (dim.) (11.12.6.2.3)
CR_{cr}	=	long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.) (11.10.6.4.4b)
CR_u	=	short-term connection strength reduction factor to account for reduced ultimate strength resulting from the connection (dim.) (11.10.6.4.4b)
C_u	=	coefficient of uniformity defined as ratio of the particle size of soil that is 60 percent finer in size (D_{60}) to the particle size of soil that is ten percent finer in size (D_{10}) (dim.) (11.10.6.3.2)
D	=	design embedment depth of vertical element (ft); diameter of bar or wire (in.) (11.6.5.5) (C11.8.4.1)
D'_C	=	effective equivalent diameter of conical slip surface at soil nail head (ft) (11.12.6.2.3)
D_C	=	equivalent diameter of conical slip surface at soil nail head (ft) (11.12.6.2.3)
D_{DH}	=	drill hole diameter (in.) (11.9.4.2) (11.12.6.2.3) (11.12.5.2)
D_o	=	embedment for which net passive pressure is sufficient to provide moment equilibrium (ft) (C11.8.4.1)
D_{SC}	=	diameter of the shaft of a headed stud (in.) (11.12.6.2.4)
D_{SH}	=	diameter of the head of stud (in.) (11.12.6.2.4)
D_{tmax}	=	T_{max} distribution factor (dim.) (11.10.6.2.1e)
D_{tmax0}	=	T_{max} distribution factor magnitude at top of wall at wall face (dim.) (11.10.6.2.1e)
D_{10}	=	particle size at which 10 percent of the soil particles by weight pass through (in.) (11.10.6.3.2)
D_{60}	=	particle size at which 60 percent of the soil particles by weight pass through (in.) (11.10.6.3.2)
d	=	the lateral wall displacement or maximum wall displacement allowed (in.); fill thickness above wall (ft) (11.10.4.2) (A11.5.1) (A11.5.3)
d_f	=	distance from the outer edge of a final facing section in compression to the centroid of the reinforcement (in.) (11.12.6.2.2)
d_i	=	distance from the outer edge of an initial facing section in compression to the centroid of the reinforcement (in.) (11.12.6.2.2)
E_c	=	thickness of metal reinforcement at end of service life (mil.) (11.10.6.4.2a)
E_n	=	nominal thickness of steel reinforcement at construction (mil.) (11.10.6.4.2a)
E_s	=	sacrificial thickness of metal expected to be lost by uniform corrosion during service life (mil.) (11.10.6.4.2a)
e	=	eccentricity of load from centerline of foundation (ft) (11.10.6.2.1d)
F_T	=	resultant force of active lateral earth pressure (kips/ft) (11.6.3.2)
F_p	=	static lateral force due to a concentrated surcharge load (kips/ft) (C11.6.5.1)
F_v	=	site class adjustment factor for the 1-sec spectral acceleration (dim.) (A11.5.2)
F_y	=	minimum yield strength of steel (ksi) (11.10.6.4.3a)
F^*	=	reinforcement pullout friction factor (dim.) (11.10.6.3.2)
f'_c	=	compressive strength of concrete (ksi) (11.12.6.2.3)
f_y	=	yield strength of steel (ksi) (11.12.6.1)
f_{y-hs}	=	yield strength of headed stud (ksi) (11.12.6.2.4)
G_u	=	distance from center of gravity of a horizontal segmental facing block unit, including aggregate fill, measured from the front of the unit (ft) (11.10.6.4.4b)
H	=	height of wall (ft) (11.6.5.2.2) (A11.3.1)
H'	=	80 percent of the height of the wall, as measured from the bottom of the heel of the wall to the ground surface directly above the wall heel (or the total wall height at the back of the reinforced soil zone for MSE walls) (ft) (A11.5.3)
H_h	=	hinge height for segmental facing (ft) (11.10.6.4.4b)
H_{ref}	=	reference wall height (ft) (11.10.6.2.1e)
H_u	=	segmental facing block unit height (ft) (11.10.6.4.4b)
H_1	=	equivalent wall height (ft) (11.10.6.3.1)
h	=	vertical distance between ground surface and wall base at the back of wall heel (ft); thickness of facing (in.) (11.6.3.2) (11.10.6.2.1d) (11.10.7.1) (11.12.6.2.2) (A11.3.1) (A11.5.2)
h_a	=	distance between the base of the wall, or the mudline in front of the wall, and the resultant active seismic earth pressure force (ft) (A11.3.1)
h_c	=	effective depth of conical surface (ft) (11.12.6.2.3)

h_{eff}	=	equivalent height of an unjointed facing column that is approximately 100 percent efficient in transmitting moment through the height of the facing column (ft) (C11.10.6.2.1e)
h_f	=	thickness of final facing (in.) (11.12.6.2.2)
h_i	=	height of reinforced soil zone contributing horizontal load to reinforcement at level i (ft); thickness of initial facing (in.) (11.12.6.2.2)
h_p	=	vertical distance between the wall base and the static surcharge lateral force, F_p (ft) (11.10.10.1)
i	=	backfill slope angle (degrees) (A11.3.1)
i_b	=	slope of facing base downward into backfill (degrees) (11.10.6.4.4b)
J_{ave}	=	average secant tensile stiffness of all n reinforcement layers in wall (kips/ft) (11.10.6.2.1e)
J_i	=	reinforcement layer secant stiffness (kips/ft) (11.10.4.3)
K	=	seismic passive pressure coefficient (dim.) (A11.3.1)
K_{AE}	=	seismic active pressure coefficient (dim.) (A11.3.1)
k_a	=	active earth pressure coefficient (dim.) (11.8.4.1)
k_{af}	=	active earth pressure coefficient of backfill (dim.) (11.10.5.2)
k_{avh}	=	active earth pressure coefficient for a wall with a vertical face (dim.) (11.10.6.2.1e)
k_h	=	horizontal seismic acceleration coefficient (dim.) (11.6.5.2.2) (11.8.6.2) (A11.3.1)
k_{h0}	=	horizontal seismic acceleration coefficient at zero displacement (dim.) (11.6.5.2)
k_o	=	horizontal at-rest earth pressure coefficient of reinforced fill (dim.) (11.10.6.2.1d)
k_p	=	passive earth pressure coefficient (dim.) (C11.8.4.1)
k_v	=	vertical seismic acceleration coefficient (dim.) (11.6.5.3) (A11.3.1)
k_r	=	horizontal earth pressure coefficient of reinforced fill (dim.) (11.10.5.2)
k_y	=	yield acceleration in sliding block analysis that results in sliding of the wall (dim) (A11.5.2)
L	=	spacing between vertical elements or facing supports (ft); length of reinforcing elements in an MSE wall and correspondingly its foundation (ft) (C11.8.5.2) (11.10.2)
L_{BP}	=	length of a bearing plate (ft) (11.12.6.2.3)
L_P	=	pullout length behind slip surface (ft) (11.12.5.2) (C11.12.5.2)
L_S	=	length of headed stud (ft) (11.12.6.2.4)
L_a	=	length of reinforcement in active zone (ft) (11.10.2)
L_b	=	anchor bond length (ft) (11.9.4.2)
L_e	=	length of reinforcement in resistance zone (ft) (11.10.2)
L_{ei}	=	effective reinforcement length for layer i (ft) (11.10.7.2)
M	=	moment magnitude of design earthquake (dim.) (A11.5.3)
$MARV$	=	minimum average roll value (11.10.6.4.3b)
M_{max}	=	maximum bending moment in vertical wall element or facing (kip-ft or kip-ft/ft) (C11.8.5.2)
N	=	standard penetration resistance from <i>SPT</i> (blows/ft) (A11.5.3)
N_H	=	number of headed studs (dim.) (11.12.6.2.4)
n	=	total number of reinforcement layers in the wall (dim) (11.10.6.2.1e) (11.10.7.2)
P_{AE}	=	dynamic active horizontal thrust, including static earth pressure (kips/ft) (11.6.5.1) (C11.9.6) (A11.3)
PGA	=	peak ground acceleration (dim.) (11.6.5.2.1) (A11.5)
PGV	=	peak ground velocity (in./sec) (A11.5.2)
P_H	=	lateral force due to superstructure or other concentrated loads (kips/ft) (11.10.10.1)
P_{IR}	=	horizontal inertial force (kips/ft) (11.10.7.1)
P_{PE}	=	dynamic passive horizontal thrust, including static earth pressure (kips/ft) (11.8.6.2)
P_a	=	resultant active earth pressure force per unit width of wall (kips/ft); atmospheric pressure at sea level (ksf) (11.8.6.2) (11.10.6.2.1e)
P_b	=	factored pressure inside bin module (ksf) (11.11.5.1)
P_i	=	internal inertial force, due to the weight of the backfill within the active zone (kips/ft) (11.10.7.2)
P_{ir}	=	horizontal inertial force caused by acceleration of reinforced backfill (kips/ft) (11.10.7.1)
P_{is}	=	internal inertial force caused by acceleration of sloping surcharge (kips/ft) (11.10.7.1)
P_r	=	ultimate soil reinforcement pullout resistance per unit of reinforcement width (kips/ft) (C11.10.6.3.2)
P_{seis}	=	total lateral force applied to a wall during seismic loading (kips/ft) (11.6.5.1)
P_v	=	load on strip footing (kips/ft) (11.10.10.1)
p	=	average lateral pressure, including earth, surcharge, and water pressure, acting on the section of wall element being considered (ksf) (C11.8.5.2)
Q_R	=	factored anchor resistance (kips) (11.9.4.2)
Q_n	=	nominal (ultimate) anchor resistance (kips) (11.9.4.2)
q_s	=	surcharge pressure (ksf) (C11.9.3.1)
q_u	=	bond strength of soil nails (ksi) (11.12.5.2)
R	=	resultant force at base of wall (kips/ft) (11.6.3.2)

R_{BH}	=	basal heave ratio (C11.9.3.1)
R_R	=	factored resistance (kips or kips/ft) (11.5.5)
R_c	=	reinforcement coverage ratio (dim.) (11.10.6.3.2) (11.10.6.4.1)
R_{FF}	=	nominal resistance of soil nail to flexure (i.e., bending) of facing (kip) (11.12.6.2.2)
R_{FH}	=	nominal tensile resistance of headed studs located in final facing (kip) (11.12.6.2.4)
RF_{ID}	=	strength reduction factor to account for installation damage to reinforcement (dim.) (11.10.6.4.3b)
R_{FP}	=	nominal punching shear resistance of facing (kip) (11.12.6.2.3)
R_{PO}	=	nominal pullout resistance of soil nail (kip) (11.12.5.2)
R_T	=	nominal tensile resistance of tendon (kip) (11.12.6.1)
RF	=	combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical/biological aging of geosynthetic reinforcements (dim.) (11.10.6.4.3b)
RF_{CR}	=	strength reduction factor to prevent long-term creep rupture of reinforcement (dim.) (11.10.6.4.3b)
RF_D	=	strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (dim.) (11.10.6.4.3b)
S	=	average height of soil surcharge within 0.7H of back of wall face (ft) (11.10.6.2.1a)
S_{HS}	=	spacing of headed studs (ft) (11.12.6.2.3)
S_a	=	the five percent damped spectral acceleration coefficient from the site response spectra (A11.5.3)
S_{global}	=	global reinforcement stiffness (ksf) (11.10.6.2.1e)
S_h	=	horizontal reinforcement spacing (ft); horizontal spacing of soil nails (ft) (11.10.6.4.1) (C11.12.1) (C11.12.10) (11.12.6.2.2)
S_{rs}	=	ultimate reinforcement tensile resistance required to resist static load component (kips/ft) (11.10.7.2)
S_{rt}	=	ultimate reinforcement tensile resistance required to resist transient load component (kips/ft) (11.10.7.2)
S_t	=	spacing between transverse grid elements (in.) (11.10.6.3.2)
S_u	=	undrained shear strength (ksf) (C11.9.5.2)
S_v	=	vertical spacing of reinforcements, or vertical tributary layer thickness (ft); vertical spacing of soil nails (ft) (11.10.6.2.1b) (11.10.10.1) (C11.12.1)
S_1	=	1-sec spectral acceleration coefficient (dim.) (A11.5.2)
T_{ac}	=	nominal long-term reinforcement/facing connection design strength (kips/ft) (11.10.6.4.1)
T_{at}	=	nominal long-term reinforcement design strength (kips/ft) (11.10.6.4.1)
T_{crc}	=	creep-reduced connection strength per unit of reinforcement width determined from the stress rupture envelope at the specified design life as produced from a series of long-term connection creep tests (kips/ft) (11.10.6.4.4b)
T_{lot}	=	ultimate wide-width tensile strength per unit of reinforcement width (ASTM D4595 or D6637) for the reinforcement material lot used for the connection strength testing (kips/ft) (11.10.6.4.4b)
T_{max}	=	applied load to reinforcement (kips/ft) (11.10.6.2.1)
T_{maxsn}	=	maximum soil nail force (kip) (C11.12.2)
T_{md}	=	factored incremental dynamic inertia force (kips/ft) (11.10.7.2)
T_{msmx}	=	the maximum value of reinforcement load T_{max} within the wall section (kips/ft) (C11.10.6.2.1e)
T_o	=	factored tensile load at reinforcement/facing connection (kips/ft) (11.10.6.2.2)
T_{osn}	=	tensile force at the nail head (kip) (11.12.6.2.2)
T_s	=	fundamental period of wall (sec) (A11.5.3)
T_{total}	=	total load on reinforcement layer (static & dynamic) per unit width of wall (kips/ft) (11.10.7.2)
T_{totalf}	=	total factored load in the soil reinforcement (kips/ft) (11.10.10.1)
T_{ult}	=	ultimate tensile strength of reinforcement (kips/ft) (11.10.6.4.3b)
$T_{ultconn}$	=	ultimate connection strength per unit of reinforcement width (kips/ft) (11.10.6.4.4b)
t_{SH}	=	thickness of the head of stud (ft) (11.12.6.2.4)
V_F	=	punching shear force acting through facing (kip) (11.12.6.2.3)
V_s	=	shear wave velocity of the soil behind the wall (ft/sec) (A11.5.3)
V_1	=	weight of soil carried by wall heel, not including weight of soil surcharge (kips/ft) (11.6.3.2)
V_2	=	weight of soil surcharge directly above wall heel (kips/ft) (11.6.3.2)
W_s	=	weight of the soil that is immediately above the wall, including the wall heel (kips/ft) (11.6.5.1)
W_u	=	unit width of segmental facing (ft) (11.10.6.4.4b)
W_w	=	weight of the wall (kips/ft) (11.6.5.1)
W_1	=	weight of wall stem (kips/ft) (11.6.3.2)
W_2	=	weight of wall footing or base (kips/ft) (11.6.3.2)
x	=	spacing between vertical element supports (ft) (11.9.5.2)
Z	=	depth below effective top of wall or to reinforcement (ft) (11.10.6.2.1) (11.10.6.3.2)
Z_p	=	depth of soil at reinforcement layer at beginning of resistance zone for pullout calculation (ft) (11.10.6.2.1)

z_b	=	depth below top of wall at wall face where D_{max} becomes equal to 1.0 (and below which D_{max} equals 1.0) (ft) (11.10.6.2.1e)
α	=	scale effect correction factor, or wall height acceleration reduction factor for wave scattering (dim.) (11.10.6.3.2) (A11.5.2)
β	=	slope of backfill (degrees); slope of wall to the vertical, negative as shown (degrees) (11.10.7.1) (A11.3.1)
γ'	=	effective soil unit weight (ksf) (C11.8.4.1)
γ_{CT}	=	load factor for vehicular impact loads (dim.) (11.10.10.2)
γ_{EQ}	=	load factor for live load applied simultaneously with seismic loads in Article 3.4.1 (dim.) (C11.5.6) (11.6.5)
γ_{LS}	=	load factor for live load surcharge (dim.) (11.10.6.4.1) (B11.2)
γ_f	=	unit weight of backfill (ksf) (11.10.5.2)
γ_p	=	load factor for vertical earth pressure in Article 3.4.1 (dim.) (11.10.6.2.1) (11.12.5.2)
γ_{p-ES}	=	load factor for earth surcharge, <i>ES</i> , in Table 3.4.1-2 (11.10.10.1)
γ_{p-EV}	=	load factor for vertical earth pressure, <i>EV</i> , in Article 3.4.1 (dim.) (11.10.6.2.1)
γ_{p-EVsf}	=	load factor for prediction of T_{max} for the soil failure limit state (dim.) (11.10.4.3)
γ	=	unit weight of soil (ksf) (A11.3.1)
γ_r	=	unit weight of reinforced fill (ksf) (11.10.6.2.1)
γ_{seis}	=	the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load for Extreme Event I (dim.) (11.10.7.2)
$\Delta\sigma_H$	=	horizontal stress on reinforcement from concentrated horizontal surcharge (ksf); traffic barrier impact stress applied over reinforcement tributary area (ksf) (11.10.6.2.1) (11.10.10.1)
$\Delta\sigma_v$	=	vertical stress due to footing load (ksf) (11.10.10.1)
δ	=	wall-backfill interface friction angle (degrees) (11.5.5) (A11.3.1)
δ_{max}	=	maximum displacement (ft) (C11.10.4.2)
δ_R	=	relative displacement coefficient (C11.10.4.2)
ΣV	=	the summation of vertical forces (11.6.3.2)
ε	=	a normally distributed random variable with zero mean and a standard deviation of 0.66. (A11.5.3)
ε_{max}	=	maximum acceptable strain in the wall cross-section corresponding to T_{max} in any reinforcement layer (percent) (11.10.4.3)
ε_{rein}	=	the reinforcement strain in any individual reinforcement layer corresponding to T_{max} (percent) (11.10.4.3)
θ	=	wall batter from horizontal (degrees) (C11.10.6.2.1c)
θ_{MO}	=	arc tan [$k_h/(1-k_v)$] for M-O analysis (degrees) (11.6.5.3) (A11.3.1)
ρ	=	soil-reinforcement angle of friction (degrees) (11.10.5.3)
ρ_{ij}	=	reinforcement ratio (percent) (C11.12.6.2.2)
σ_H	=	factored horizontal stress at reinforcement level (ksf) (11.10.10.1)
σ_v	=	vertical stress in soil at reinforcement level of base of wall (ksf) (11.10.6.2.1a) (11.10.6.3.2)
σ_{v1}	=	vertical soil stress over effective base width (ksf) (11.10.10.1)
σ_1	=	stress at reinforcement level due to MSE wall backfill self-weight (ksf) (11.10.6.2.1a) (11.10.6.3.2)
σ_2	=	average stress at top of MSE wall backfill due to soil surcharge (ksf) (11.10.6.2.1a) (11.10.6.3.2)
τ_n	=	nominal anchor bond stress (ksf) (11.9.4.2)
Φ	=	empirically determined influence factor that captures the effect that the soil reinforcement properties, soil cohesion, and wall geometry have on T_{max} (dim.) (11.10.6.2.1e)
Φ_c	=	soil cohesion factor (dim.) (11.10.6.2.1e)
Φ_{fb}	=	facing batter factor (dim.) (C11.10.6.2.1)
Φ_{fs}	=	facing stiffness factor (dim.) (11.10.6.2.1e)
Φ_g	=	global stiffness factor (dim.) (11.10.6.2.1e)
Φ_{local}	=	local stiffness factor (dim.) (C11.10.6.2.1e)
ϕ	=	resistance factor (11.5.5) (11.5.7)
ϕ'_f	=	effective internal friction angle of soil (degrees) (C11.8.4.1)
ϕ_{FF}	=	resistance factor for flexure (dim.) (11.12.6.2.2)
ϕ_{FH}	=	resistance factor for headed stud in tension (dim.) (11.12.6.2.4)
ϕ_{FP}	=	resistance factor for punching shear in facing (dim.) (11.12.6.2.3)
ϕ_{PO}	=	resistance factor for pullout (dim.) (11.12.5.2)
ϕ_T	=	resistance factor for tension (dim.) (11.12.6.1)
ϕ_f	=	internal friction angle of foundation or backfill soil (degrees) (11.10.5.3) (A11.3.1)
ϕ_r	=	internal friction angle of reinforced fill (degrees) (11.10.5.3)

- ϕ_{sf} = resistance factor that accounts for uncertainty in the measurement of the reinforcement stiffness at the specified strain (dim.) (11.10.4.3)
- ω = wall batter due to setback of segmental facing units (degrees) (11.10.6.4.4b)

11.4—SOIL PROPERTIES AND MATERIALS

11.4.1—General

Backfill materials should be granular, free-draining materials. Where walls retain in-situ cohesive soils, drainage shall be provided to reduce hydrostatic water pressure behind the wall.

C11.4.1

Much of the knowledge and experience with MSE structures has been with select, cohesionless backfill as specified in Section 7 of the *AASHTO LRFD Bridge Construction Specifications*. Hence, knowledge about internal stress distribution, pullout resistance and failure surface shape is constrained and influenced by the unique engineering properties of granular soils. While cohesive soils have been successfully used, problems including excessive deformation and complete collapse have also occurred. Most of these problems have been attributed to poor drainage. Drainage requirements for walls constructed with poor draining soils are provided in Berg et al. (2009).

11.4.2—Determination of Soil Properties

The provisions of Articles 2.4 and 10.4 shall apply.

C11.4.2

Also see Article C10.4.

11.5—LIMIT STATES AND RESISTANCE FACTORS

11.5.1—General

Design of abutments, piers, and walls shall satisfy the criteria for the service limit state specified in Article 11.5.2, and for the strength limit state specified in Article 11.5.3.

Abutments, piers, and retaining walls shall be designed to withstand lateral earth and water pressures, including any live and dead load surcharge, the self-weight of the wall, temperature and shrinkage effects, and earthquake loads in accordance with the general principles specified in this Section.

Earth retaining structures shall be designed for a service life based on consideration of the potential long-term effects of material deterioration, seepage, stray currents, and other potentially deleterious environmental factors on each of the material components comprising the structure. For most applications, permanent retaining walls should be designed for a minimum service life of 75 years. Retaining wall applications defined as temporary shall be considered to have a service life of 36 months or less.

A greater level of safety and/or longer service life, i.e., 100 years, may be appropriate for walls which support bridge abutments, buildings, critical utilities, or other facilities for which the consequences of poor performance or failure would be severe.

Permanent structures shall be designed to retain an aesthetically pleasing appearance and be essentially maintenance free throughout their design service life.

C11.5.1

Design of walls to be essentially maintenance free does not preclude the need for periodic inspection of the wall to assess its condition throughout its design life.

11.5.2—Service Limit State

Abutments, piers, and walls shall be investigated for excessive vertical and lateral displacement at the service limit state. Tolerable vertical and lateral deformation criteria for retaining walls shall be developed based on the function and type of wall, anticipated service life, and both structural and aesthetic consequences of unacceptable movements to the wall and any potentially affected nearby structures.

The provisions of Articles 10.6.2.2, 10.7.2.2, and 10.8.2.1 shall apply to the investigation of vertical wall movements. For anchored walls, deflections shall be estimated in accordance with the provisions of Article 11.9.3.1. For MSE walls, deflections shall be estimated in accordance with the provisions of Article 11.10.4.

C11.5.2

Vertical wall movements are primarily the result of soil settlement beneath the wall. For gravity and semigravity walls, lateral movement results from a combination of differential vertical settlement between the heel and the toe of the wall and the rotation necessary to develop active earth pressure conditions (see Article C3.11.1).

Tolerable total and differential vertical deformations for a particular retaining wall are dependent on the ability of the wall to deflect without causing damage to the wall elements or adjacent structures, or without exhibiting unsightly deformations.

Surveys of the performance of bridges indicate that horizontal abutment movements less than 1.5 in. can usually be tolerated by bridge superstructures without significant damage, as reported in Bozozuk (1978); Walkinshaw (1978); Moulton et al. (1985); and Wahls (1990). Earth pressures used in design of abutments should be selected consistent with the requirement that the abutment should not move more than 1.5 in. laterally.

Regarding impact to the wall itself, differential settlement along the length of the wall and to some extent from front to back of wall is the best indicator of the potential for retaining wall structural damage or overstress. Wall facing stiffness and ability to adjust incrementally to movement affect the ability of a given wall system to tolerate differential movements. The total and differential vertical deformation of a retaining wall should be small for rigid gravity and semigravity retaining walls, and for soldier pile walls with a cast-in-place facing. For walls with anchors, any downward movement can cause significant stress relaxation of the anchors.

MSE walls can tolerate larger total and differential vertical deflections than rigid walls. The amount of total and differential vertical deflection that can be tolerated depends on the wall facing material, configuration, and timing of facing construction. A cast-in-place facing has the same vertical deformation limitations as the more rigid retaining wall systems. However, an MSE wall with a cast-in-place facing can be specified with a waiting period before the cast-in-place facing is constructed so that vertical (as well as horizontal) deformations have time to occur. An MSE wall with welded wire or geosynthetic facing can tolerate the most deformation. The deformation tolerance of other MSE wall facing systems, such as precast concrete panels and dry cast concrete blocks, depends on the spacing or cushioning provided between the facing elements and their dimensions. Guidance is provided in Article C11.10.4.1.

11.5.3—Strength Limit State

Abutments, walls, and piers shall be investigated at the strength limit states using Eq. 1.3.2.1-1 for:

- bearing resistance failure,

- lateral sliding,
- loss of base contact due to eccentric loading,
- pullout failure of anchors or soil reinforcements,
- structural failure, and
- overall stability.

11.5.4—Extreme Event Limit State

11.5.4.1—General Requirements

Abutments, walls, and piers shall be investigated at the extreme event limit state for:

- overall stability failure,
- bearing resistance failure,
- lateral sliding,
- loss of base contact due to eccentric loading,
- pullout failure of anchors or soil reinforcements, and
- structural failure.

The design peak ground acceleration coefficient, A_s , used for seismic design of retaining walls shall be determined in accordance with Article 3.10.

11.5.4.2—Extreme Event I, No Analysis

A seismic design shall not be considered mandatory for walls located in Seismic Zones 1 through 3, or for walls at sites where A_s is less than or equal to 0.4, unless one or more of the following is true:

- Liquefaction induced lateral spreading or slope failure, or seismically induced slope failure, due to the presence of sensitive clays that lose strength during the seismic shaking, may impact the stability of the wall for the design earthquake.
- The wall supports another structure that is required, based on the applicable design code or specification for the supported structure, to be designed for seismic loading and poor seismic performance of the wall could impact the seismic performance of that structure.

The no-seismic-analysis option should be limited to internal and external seismic stability design of the wall. If the wall is part of a bigger slope, overall seismic stability of the wall and slope combination should still be evaluated.

These no-seismic-analysis provisions shall not be considered applicable to walls functioning as support piers for bridges.

C11.5.4.1

The levels of peak ground acceleration at the ground surface in some areas will be low enough that a check on seismic loading is not required as other limit states will control the design.

C11.5.4.2

Article 11.5.4.2, related to specific seismic zones, may also be considered applicable to the corresponding Seismic design categories (SDCs) A, B, and C, if using AASHTO's *Guide Specifications for LRFD Seismic Bridge Design*.

A summary of previous performance of walls in earthquakes, as well as key research findings that provide support for the provisions in Article 11.5.4.2, is provided in Appendix A11. In general, wall performance in past earthquakes has been very good, even in the largest, most damaging earthquakes, and cases where either wall collapse or severe wall displacements have occurred are rare. For those cases where collapse or severe displacement of walls did occur, those cases were mostly limited to situations where significant liquefaction occurred, where soil conditions behind or below the wall were very poor (e.g., soft silts and clays, marginally stable soils, water build up behind the wall) and ground accelerations were high, or where the wall was subjected to direct shear displacement of the fault. Furthermore, most of those failures were limited to walls that were very old. These wall failure situations are all well outside the limits specified in Article 11.5.4.2 where these specifications allow the designer to not conduct a detailed wall seismic design. However, walls meeting the requirements in Article 11.5.4.2 that allow a seismic analysis to not be conducted have demonstrated consistently good performance in past earthquakes.

Based on previous experience, walls that form tunnel portals have tended to exhibit more damage due to

earthquakes than free standing walls. It is likely that the presence of the tunnel restricts the ability of the portal wall to move, increasing the seismic forces to which the wall is subjected. Therefore, a more detailed seismic analysis of tunnel portal walls should be considered even if the walls meet all the other no seismic analysis conditions specified in Article 11.5.4.2.

For walls that cross an active fault which could result in significant differential movement within the wall, a detailed seismic analysis should be considered even if the wall is located in Seismic Zones 1, 2, or 3.

Examples of other structures include bridges (e.g., the abutment foundation), buildings, pipelines or major utilities, pipe arches, or dams. If the wall supports another wall, a seismic design is not required for the lower wall, provided that the upper and lower wall can be designed as a single tiered structure and the limitations on the tiered structure for the provisions in Article 11.5.4.2, if in Seismic Zone 3 or lower, are met.

Based on past experience in earthquakes, wall corners and short-radius turns, defined as an alignment change with an enclosed angle of 120 degrees or less, tend to exhibit greater damage than free standing walls with generally straight alignments due to potentially greater stiffness at the corner, or may separate at the corner due to lack of connectivity between wall sections at the corner. The seismic details discussed in Articles C11.6.5.6 and C11.10.7.4 will help to reduce the potential problems at corners that have occurred in past earthquakes. Note that the enclosed angle of the corner or short-radius turn can either be internal or external to the wall.

A seismic analysis should be considered for Seismic Zone 2 or higher if either of the following is greater than 30.0 ft:

- the exposed wall height plus the average depth over the width of the wall of any soil surcharge present, or
- for tiered walls, the sum of the exposed height of all the tiers plus the average soil surcharge depth.

A seismic analysis should be considered if in Seismic Zone 2 or higher, and if, for gravity and semigravity walls, the wall backfill does not meet the requirements of Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*, due to the possibility that the backfill will not be adequately drained to prevent water build up in the backfill.

For Seismic Zone 2 or higher, if a seismic design is not conducted, it is still important to use good seismic details as specified in Articles 11.6.5.6 and 11.10.7.4.

If the wall is part of a bigger slope that potentially could fail during seismic loading, the overall seismic stability of the wall and slope as defined in Article 11.6.3.7 should be evaluated, as specified in Articles 11.5.4.1 and 11.5.8. If the wall is determined to have only a minor destabilizing effect on the overall

11.5.5—Resistance Requirement

Abutments, piers, and retaining structures and their foundations and other supporting elements shall be proportioned by the appropriate methods specified in Articles 11.6, 11.7, 11.8, 11.9, 11.10, 11.11, or 11.12 so that their resistance satisfies Article 11.5.6.

The factored resistance, R_R , calculated for each applicable limit state shall be the nominal resistance, R_n , multiplied by an appropriate resistance factor, ϕ , specified in Table 11.5.7-1.

11.5.6—Load Combinations and Load Factors

Abutments, piers, and retaining structures and their foundations and other supporting elements shall be proportioned for all applicable load combinations specified in Article 3.4.1.

stability of the slope during seismic loading, for example, a wall placed within a large slope or existing landslide that is marginally stable during static loading, it may not be practical to design the wall to be stable for overall stability for the Extreme Event I limit state. Addressing the landslide overall stability during seismic loading should be considered a separate effort not specifically addressed by these Specifications.

C11.5.5

Procedures for calculating nominal resistance are provided in Articles 11.6, 11.7, 11.8, 11.9, 11.10, 11.11, and 11.12 for abutments and retaining walls, piers, nongravity cantilevered walls, anchored walls, mechanically stabilized earth walls, prefabricated modular walls, and soil nail walls, respectively.

C11.5.6

Figures C11.5.6-1 and C11.5.6-2 show the typical application of load factors to produce the total extreme factored force effect for external stability of retaining walls for the strength limit state. Where live load surcharge is applicable, the factored surcharge force is generally included over the backfill immediately above the wall only for evaluation of foundation bearing resistance and structure design, as shown in Figure C11.5.6-3. The live load surcharge is not included over the backfill for evaluation of eccentricity, sliding or other failure mechanisms for which such surcharge would represent added resistance to failure. Likewise, the live load on a bridge abutment is included only for evaluation of foundation bearing resistance and structure design. The load factor for live load surcharge is the same for both vertical and horizontal load effects. Figure C11.5.6-3 is also applicable to seismic loading (i.e., Extreme Event I), except that the load factor for live load surcharge is γ_{EQ} instead of LS .

Figure C11.5.6-4 shows the typical application of load factors to produce the total extreme factored force effect for external stability of retaining walls for the Extreme Event I limit state.

The permanent and transient loads and forces shown in the figures include, but are not limited to:

- Permanent Loads
 - DC = dead load of structural components and nonstructural attachments
 - DW = dead load of wearing surfaces and utilities
 - EH = horizontal earth pressure load
 - ES = earth surcharge load
 - EV = vertical pressure from dead load of earth fill

- Transient Loads

LS = live load surcharge

WA = water load and stream pressure

Loads due to water and stream pressure are not shown in these figures. However, the load factor WA as specified in Table 3.4.1-1 is always 1.0. Design specifications to account for the destabilizing effect caused by the presence of water are provided in Article 3.11.3.

For the Extreme Event I limit state, the peak seismic lateral pressures acting on the wall should not be based on the maximum ground water elevation due to the low probability that the design peak seismic acceleration would be combined with the maximum ground water level. Instead, it is more appropriate to use the time-averaged mean groundwater elevation or a reasonable engineering estimate of this elevation.

Figure C11.5.6-1—Typical Application of Load Factors for Bearing Resistance

Figure C11.5.6-2—Typical Application of Load Factors for Sliding and Eccentricity

For seismic loading effects on lateral earth pressure, the seismic load factor shall be applied to the entire lateral earth pressure load created by the earth mass retained by the wall or abutment. For any surcharge loads acting on the wall (e.g., *ES*) in combination with seismic load, *EQ*, the load factor for seismic loads, shall be applied.

Seismic loading of an earth mass retained by a wall is calculated using an extension of Coulomb theory or by limit equilibrium slope stability methods. The seismic loading causes the active soil wedge to increase, resulting in increased total load. The static loading cannot be separated from the seismic loading in this analysis, other than by artificial means through subtracting the static earth pressure from the total earth pressure calculated for seismic loading. Past allowable stress design practice has been to apply a single reduced safety factor to the entire lateral earth load combination. Therefore, one seismic load factor (typically a load factor of 1.0) is applied to the total earth pressure that occurs during seismic loading.

Regarding other loads acting in combination with the seismic loading and earth pressure, the load combination philosophy described for earth pressure also applies to be consistent with past allowable stress design practice for a no collapse design objective.

11.5.7—Resistance Factors—Service and Strength

Resistance factors for the service limit states shall be taken as 1.0.

For the strength limit state, the resistance factors provided in Table 11.5.7-1 shall be used for wall design, unless region-specific values or substantial successful experience is available to justify higher values. Resistance factors for geotechnical design of foundations that may be needed for wall support, unless specifically identified in Table 11.5.7-1, are as specified in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, and 10.5.5.2.4-1.

If methods other than those prescribed in these Specifications are used to estimate resistance, the resistance factors chosen shall provide the same reliability as those given in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, 10.5.5.2.4-1, and Table 11.5.7-1.

Vertical elements, such as soldier piles, tangent-piles, and slurry trench concrete walls shall be treated as either shallow or deep foundations, as appropriate, for purposes of estimating bearing resistance, using procedures described in Articles 10.6, 10.7, and 10.8.

Some increase in the prescribed resistance factors may be appropriate for design of temporary walls consistent with increased allowable stresses for temporary structures in allowable stress design.

C11.5.7

The resistance factors given in Table 11.5.7-1 for steel reinforced MSE walls, other than those referenced back to Section 10, were calculated by direct correlation to allowable stress design rather than reliability theory. However, for geosynthetic reinforced walls, since the specified method for calculating reinforcement loads is relatively new (i.e., the Stiffness Method—see Article 11.10.6.2.1), reliability theory calibrated resistance factors are provided in Table 11.5.7-1 assuming the load factor for the Stiffness Method (γ_{p-EV}), is 1.35. For the Simplified Method, applicable load and resistance factors are provided in Appendix B11.

Comments regarding the differences between extensible and inextensible reinforcement can be found in Article C11.10.6.2.

Region-specific resistance factor values should be determined based on substantial statistical data combined with calibration or substantial successful experience to justify higher values. Smaller resistance factors should be used if site or material variability is anticipated to be unusually high or if design assumptions are required that increase design uncertainty that has not been mitigated through conservative selection of design parameters. See Allen et al. (2005) for additional guidance on calibration of resistance factors.

The evaluation of overall stability of walls or earth slopes with or without a foundation unit should be investigated at the strength limit state using γ_p for overall stability as specified in Article 3.4.1, and an appropriate resistance factor as specified in Article 11.6.3.7.

Table 11.5.7-1—Strength Limit State Resistance Factors for Permanent Retaining Walls

Wall-Type and Condition		Resistance Factor
Nongravity Cantilevered and Anchored Walls		
Axial compressive resistance of vertical elements		Article 10.5 applies
Passive resistance of vertical elements		0.75
Pullout resistance of anchors ⁽¹⁾	- Cohesionless (granular) soils - Cohesive soils - Rock	0.65 ⁽¹⁾ 0.70 ⁽¹⁾ 0.50 ⁽¹⁾
Pullout resistance of anchors ⁽²⁾	Where proof tests are conducted	1.0 ⁽²⁾
Tensile resistance of anchor tendon	- Mild steel (e.g., ASTM A615 bars) - High-strength steel (e.g., ASTM A722 bars)	0.90 ⁽³⁾ 0.80 ⁽³⁾
Overall stability, soil failure		Article 11.6.3.7 applies
Flexural capacity of vertical elements		0.90
Mechanically Stabilized Earth Walls, Gravity Walls, and Semigravity Walls		
Bearing resistance	- Gravity and semigravity walls - MSE walls	0.55 0.65
Sliding	- Soil shear component - Passive component	1.0 0.50
Tensile resistance of metallic reinforcement and connectors	Strip reinforcements ⁽⁴⁾ Grid reinforcements ⁽⁴⁾⁽⁵⁾	0.75 0.65
Tensile resistance of geosynthetic reinforcement and connectors	- Geotextile and geogrid reinforcements - Geostrip reinforcements	0.80 0.55
Pullout resistance of metallic reinforcement	- Steel strip reinforcements - Steel grid reinforcements	0.90 0.90
Pullout resistance of geosynthetic reinforcement	- Geotextiles and geogrids - Geostrip reinforcements	0.70 0.70
Service Limit, for soil failure using stiffness method		1.0
Overall and compound stability	Soil failure	Article 11.6.3.7 applies
Tensile Resistance	- Metallic reinforcement (steel strips)⁽⁴⁾ - Metallic reinforcement (steel grid)⁽⁴⁾⁽⁵⁾ - Geosynthetic reinforcement (geotextiles, geogrids, and geostrips)	0.75 0.65 0.90
Pullout resistance	All reinforcements	0.90
Prefabricated Modular Walls		
Bearing resistance		0.55
Sliding	- Soil shear component - Passive component	1.0 0.50
Overall stability, soil failure		Article 11.6.3.7 applies
Soil Nail Walls ⁽⁶⁾		
Lateral sliding		1.00
Overall and Compound stability, soil failure		Article 11.6.3.7 applies
Tensile resistance of nail tendon	Mild steel bars (Grade 75) High resistance bars (Grades 95 and 150)	0.75 0.65
Pullout resistance of nail		0.65
Facing flexure	Initial and final facing	0.90
Facing punching shear	Initial and final facing	0.90
Tensile resistance of headed stud	A307 steel bolt ⁽⁷⁾ A325 steel bolt	0.70 0.80

(1) Apply to presumptive ultimate unit bond stresses for preliminary design only in Article C11.9.4.2.

(2) Apply where proof test(s) are conducted on every production anchor to a load of 1.0 or greater times the factored load on the anchor.

(3) Apply to maximum proof test load for the anchor. For mild steel, apply resistance factor to F_y . For high-strength steel, apply the resistance factor to guaranteed ultimate tensile strength.

(continued on next page)

Table 11.5.7-1 (cont.)—Strength Limit State Resistance Factors for Permanent Retaining Walls

- (4) Apply to gross cross-section less sacrificial area. For sections with holes, reduce gross area in accordance with Article 6.8.3 and apply to net section less sacrificial area.
- (5) Applies to grid reinforcements connected to a rigid facing element, e.g., a concrete panel or block. For grid reinforcements connected to a flexible facing mat or which are continuous with the facing mat, use the resistance factor for strip reinforcements.
- (6) Additional, special cases of limit states, as well as corresponding resistance factors, for soil nail walls are presented in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).
- (7) Equivalent to AWS D1.1/D1.1M Type B studs, with $f_y = 60$ ksi.

11.5.8—Resistance Factors—Extreme Event Limit State

Unless otherwise specified, all resistance factors shall be taken as 1.0 when investigating the extreme event limit state.

For overall stability of the retaining wall when earthquake loading is included, a resistance factor, ϕ , of 0.9 shall be used. For bearing resistance, a resistance factor of 0.8 shall be used for gravity and semigravity walls and 0.9 for MSE walls.

For tensile resistance of metallic reinforcement and connectors, when earthquake loading is included, the following resistance factors shall be used:

- Strip reinforcements, $\phi = 1.0$
- Grid reinforcement, $\phi = 0.85$

Table 11.5.7-1 Notes 4 and 5 also apply to these resistance factors for metallic reinforcements.

For tensile and pullout resistance of geosynthetic reinforcement and connectors, a resistance factor, ϕ , of 1.0 shall be used.

For pullout resistance of metallic reinforcement, a resistance factor, ϕ , of 1.20 shall be used.

C11.5.8

A resistance factor of 1.0 is recommended for the extreme event limit state in view of the unlikely occurrence of the loading associated with the design earthquake. The choice of 1.0 is influenced by the following factors:

- For competent soils that are not expected to lose strength during seismic loading (e.g., due to liquefaction of saturated cohesionless soils or strength reduction of sensitive clays), the use of static strengths for seismic loading is usually conservative, as rate-of-loading effects tend to increase soil strength for transient loading.
- Earthquake loads are transient in nature and hence, if soil yield occurs, the net effect is an accumulated small deformation as opposed to foundation failure. This assumes that global stability is adequate.

Using a resistance factor of 1.0 for soil assumes ductile behavior. While this is a correct assumption for many soils, it is inappropriate for brittle soils where there is a significant post-peak strength loss (e.g., stiff over-consolidated clays, sensitive soils). For such conditions, special studies will be required to determine the appropriate combination of resistance factor and soil strength.

For bearing resistance, a slightly lower resistance factor of 0.8 is recommended for gravity and semigravity walls and 0.9 for MSE walls to reduce the possibility that a bearing resistance failure could occur before the wall moves laterally in sliding, reducing the likelihood of excessive wall tilting or collapse, consistent with the design objective of no collapse.

11.6—ABUTMENTS AND CONVENTIONAL RETAINING WALLS

11.6.1—General Considerations

11.6.1.1—General

Rigid gravity and semigravity retaining walls may be used for bridge substructures or grade separation and are generally for permanent applications.

C11.6.1.1

Conventional retaining walls are generally classified as rigid gravity or semigravity walls, examples of which are shown in Figure C11.6.1.1-1. These types of walls can be effective for both cut and fill wall applications.

Rigid gravity and semigravity walls shall not be used without deep foundation support where the bearing soil/rock is prone to excessive total or differential settlement.

Excessive differential settlement, as defined in Article C11.6.2.2, can cause cracking, excessive bending or shear stresses in the wall, or rotation of the wall structure.

Figure C11.6.1.1-1—Typical Rigid Gravity and Semigravity Walls

11.6.1.2—Loading

Abutments and retaining walls shall be investigated for:

- Lateral earth and water pressures, including any live and dead load surcharge;
- The self-weight of the abutment/wall;
- Loads applied from the bridge superstructure;
- Temperature and shrinkage deformation effects; and
- Earthquake loads, as specified herein, in Section 3, and elsewhere in these Specifications.

The provisions of Articles 3.11.5 and 11.5.5 shall apply. For stability computations, the earth loads shall be multiplied by the maximum and/or minimum load factors given in Table 3.4.1-2, as appropriate.

The design shall be investigated for any combination of forces which may produce the most severe condition of loading. The design of abutments on mechanically stabilized earth and prefabricated modular walls shall be in accordance with Articles 11.10.11 and 11.11.6.

For computing load effects in abutments, the weight of filling material directly over an inclined or stepped rear face, or over the base of a reinforced concrete spread footing may be considered as part of the effective weight of the abutment.

Where spread footings are used, the rear projection shall be designed as a cantilever supported at the abutment stem and loaded with the full weight of the superimposed material, unless a more exact method is used.

C11.6.1.2

Cohesive backfills are difficult to compact. Because of the creep of cohesive soils, walls with cohesive backfills designed for active earth pressures will continue to move gradually throughout their lives, especially when the backfill is soaked by rain or rising groundwater levels. Therefore, even if wall movements are tolerable, walls backfilled with cohesive soils should be designed with extreme caution for pressures between the active and at-rest cases assuming the most unfavorable conditions. Consideration must be given for the development of pore water pressure within the soil mass in accordance with Article 3.11.3. Appropriate drainage provisions should be provided to prevent hydrostatic and seepage forces from developing behind the wall. In no case shall highly-plastic clay be used for backfill.

11.6.1.3—Integral Abutments

Integral abutments shall be designed to resist and/or absorb creep, shrinkage, and thermal deformations of the superstructure.

Movement calculations shall consider temperature, creep, and long-term prestress shortening in determining potential movements of abutments.

To avoid water intrusion behind the abutment, the approach slab should be connected directly to the abutment (not to wingwalls), and appropriate provisions should be made to provide for drainage of any entrapped water.

11.6.1.4—Wingwalls

Wingwalls may either be designed as monolithic with the abutments, or be separated from the abutment wall with an expansion joint and designed to be free standing.

The wingwall lengths shall be computed using the required roadway slopes. Wingwalls shall be of sufficient length to retain the roadway embankment and to furnish protection against erosion.

11.6.1.5—Reinforcement*11.6.1.5.1—Conventional Walls and Abutments*

Reinforcement to resist the formation of temperature and shrinkage cracks shall be designed as specified in Article 5.10.6.

11.6.1.5.2—Wingwalls

Reinforcing bars or suitable rolled sections shall be spaced across the junction between wingwalls and abutments to tie them together. Such bars shall extend into the masonry on each side of the joint far enough to develop the strength of the bar as specified for bar reinforcement, and shall vary in length so as to avoid planes of weakness in the concrete at their ends. If bars are not used, an expansion joint shall be provided and the wingwall shall be keyed into the body of the abutment.

11.6.1.6—Expansion and Contraction Joints

Contraction joints shall be provided at intervals not exceeding 30.0 ft and expansion joints at intervals not exceeding 90.0 ft for conventional retaining walls and abutments. All joints shall be filled with approved filling material to ensure the function of the joint. Joints in abutments shall be located approximately midway between the longitudinal members bearing on the abutments.

C11.6.1.3

Deformations are discussed in Article 3.12.

Integral abutments should not be constructed on spread footings founded or keyed into rock unless one end of the span is free to displace longitudinally.

11.6.2—Movement at the Service Limit State**11.6.2.1—Abutments**

The provisions of Articles 10.6.2.4, 10.6.2.5, 10.7.2.3 through 10.7.2.5, 10.8.2.2 through 10.8.2.4, and 11.5.2 shall apply as applicable.

11.6.2.2—Conventional Retaining Walls

The provisions of Articles 10.6.2.4, 10.6.2.5, 10.7.2.3 through 10.7.2.5, 10.8.2.2 through 10.8.2.4, and 11.5.2 apply as applicable.

C11.6.2.2

For a conventional reinforced concrete retaining wall, experience suggests that differential wall settlements on the order of 1 in 500 to 1 in 1,000 may overstress the wall.

11.6.3—Bearing Resistance and Stability at the Strength Limit State**11.6.3.1—General**

Abutments and retaining walls shall be proportioned to ensure stability against bearing capacity failure, overturning, and sliding. Safety against deep-seated foundation failure shall also be investigated, in accordance with the provisions of Article 10.6.3.5.

11.6.3.2—Bearing Resistance

Bearing resistance shall be investigated at the strength limit state using factored loads and resistances, assuming the following soil pressure distributions:

- Where the wall is supported by a soil foundation:

the vertical stress shall be calculated assuming a uniformly distributed pressure over an effective base area as shown in Figure 11.6.3.2-1.

The vertical stress shall be calculated as follows:

$$\sigma_v = \frac{\sum V}{B - 2e} \quad (11.6.3.2-1)$$

where:

$\sum V$ = the summation of vertical forces, and the other variables are as defined in Figure 11.6.3.2-1

- Where the wall is supported by a rock foundation:

the vertical stress shall be calculated assuming a linearly distributed pressure over an effective base area as shown in Figure 11.6.3.2-2. If the resultant is within the middle one-third of the base:

C11.6.3.2

See Figure 11.10.10.1-1 for an example of how to calculate the vertical bearing stress where the loading is more complex. Though this figure shows the application of superposition principles to mechanically stabilized earth walls, these principles can also be directly applied to conventional walls.

See Article C11.5.5 for application of load factors for bearing resistance and eccentricity.

Figure 11.6.3.2—Bearing Stress Criteria for Conventional Wall Foundations on Rock

11.6.3.3—Eccentricity Limits

For foundations on soil, the location of the resultant of the reaction forces shall be within the middle two-thirds of the base width.

For foundations on rock, the location of the resultant of the reaction forces shall be within the middle nine-tenths of the base width.

C11.6.3.3

The specified criteria for the location of the resultant, coupled with investigation of the bearing pressure, replace the investigation of the ratio of stabilizing moment to overturning moment. Location of the resultant within the middle two-thirds of the base width for foundations on soil is based on the use of plastic bearing pressure distribution for the limit state.

11.6.3.4—Subsurface Erosion

For walls constructed along rivers and streams, scour of foundation materials shall be evaluated during design, as specified in Article 2.6.4. Where potential problem conditions are anticipated, adequate protective measures shall be incorporated in the design, including, but not limited to, locating the top of the wall footing below the scour depth determined in accordance with Articles 2.6.4.4.3 and 2.6.4.5 or adding scour countermeasures to protect the wall footing.

The provisions of Article 10.6.1.2 shall apply.

The hydraulic gradient shall not exceed:

- For silts and cohesive soils:.....0.20
- For other cohesionless soils:.....0.30

C11.6.3.4

The measures most commonly used to ensure that piping does not occur are:

- seepage control,
- reduction of hydraulic gradient, and
- protective filters.

Where water seeps beneath a wall, the effects of uplift and seepage forces shall be considered.

11.6.3.5—Passive Resistance

Passive resistance shall be neglected in stability computations, unless the base of the wall extends below the depth of maximum scour, freeze-thaw, or other disturbances. In the latter case, only the embedment below the greater of these depths shall be considered effective.

Where passive resistance is utilized to ensure adequate wall stability, the calculated passive resistance of soil in front of abutments and conventional walls shall be sufficient to prevent unacceptable forward movement of the wall.

The passive resistance shall be neglected if the soil providing passive resistance is, or is likely to become soft, loose, or disturbed, or if the contact between the soil and wall is not tight.

11.6.3.6—Sliding

The provisions of Article 10.6.3.4 shall apply.

11.6.3.7—Overall Stability

The overall stability of the retaining wall, retained slope and foundation soil or rock shall be evaluated using limit equilibrium methods of analysis. The overall stability of temporary cut slopes to facilitate construction shall also be evaluated. Special exploration, testing, and analyses may be required for bridge abutments or retaining walls constructed over soft deposits.

The evaluation of overall stability of earth slopes with or without a foundation unit should be investigated at the Strength I Load Combination and an appropriate resistance factor. The resistance factor, ϕ , should be taken as:

- Where the geotechnical parameters and subsurface stratigraphy are well defined0.75
- Where the geotechnical parameters and subsurface stratigraphy are highly variable or based on limited information0.65

For anchored walls, MSE walls, and soil nail walls, this Article also applies to compound stability evaluation.

Seepage effects may be investigated by constructing a flow net, or in certain circumstances, by using generally accepted simplified methods.

C11.6.3.5

Unacceptable deformations may occur before passive resistance is mobilized. Approximate deformations required to mobilize passive resistance are discussed in Article C3.11.1, where H in Table C3.11.1-1 is the effective depth of passive restraint.

C11.6.3.7

Figure C3.4.1-1 shows a retaining wall overall stability failure. Overall stability for conventional walls (e.g., reinforced concrete gravity and semi-gravity walls) is defined as the stability of a slope soil or rock shear surface that is located outside the back of the wall, including its footing. In the case of MSE, soil nail, and anchored walls, overall stability for walls is defined as the slope soil or rock shear surface that is located behind the ends of the reinforcement elements (see Article 11.10.5.6 and Figure 11.10.5.6-1). For a definition of compound stability, see Article 11.10.5.6.

The Modified Bishop, simplified Janbu, or Spencer methods of analysis may be used.

Soft soil deposits may be subject to consolidation and/or lateral flow which could result in unacceptable long-term settlements or horizontal movements.

Available slope stability programs produce a single factor of safety, FS . The specified resistance factors are essentially the inverse of the FS that should be targeted in the slope stability program (i.e., $\phi = 0.75$ approximately corresponds to $FS = 1.3$, and $\phi = 0.65$ approximately corresponds to $FS = 1.5$). These resistance factors address the soil resistance. For anchored walls, MSE walls, and soil nail walls, the resistance factors provided in Article 11.5.7 apply to the resistance of the reinforcement elements.

11.6.4—Safety Against Structural Failure

The structural design of individual wall elements and wall foundations shall comply with the provisions of Sections 5, 6, 7, and 8.

The provisions of Article 10.6.1.3 shall be used to determine the distribution of contact pressure for structural design of footings.

11.6.5—Seismic Design for Abutments and Conventional Retaining Walls

11.6.5.1—General

Rigid gravity and semigravity retaining walls and abutments shall be designed to meet overall stability, external stability, and internal stability requirements during seismic loading. The procedures specified in Article 11.6.3.7 for overall stability, Article 11.6.3 for bearing stability, and Article 10.6.3.4 for sliding stability shall be used but including seismically induced earth pressure and inertial forces, using Extreme Event I limit state load and resistance factors as specified in Article 11.5.8.

For seismic eccentricity evaluation of walls with foundations on soil and rock, the location of the resultant of the reaction forces shall be within the middle two-thirds of the base for $\gamma_{EQ} = 0.0$ and within the middle eight-tenths of the base for $\gamma_{EQ} = 1.0$. For values of γ_{EQ} between 0.0 and 1.0, the resultant location restriction shall be obtained by linear interpolation of the values given in this Article.

For bridge abutments, the abutment seismic design should be conducted in accordance with Articles 5.2 and 6.7 of AASHTO's *Guide Specifications for LRFD Seismic Bridge Design*, but with the following exceptions:

- k_h should be determined as specified in Article 11.6.5.2, and
- lateral earth pressures should be estimated in accordance with Article 11.6.5.3.

To evaluate safety against structural failure (i.e., internal stability) for seismic design, the structural design of the wall elements shall comply with the provisions of Sections 5, 6, 7, and 8.

The total lateral force to be applied to the wall due to seismic and earth pressure loading, P_{seis} , should be determined considering the combined effect of P_{AE} and P_{IR} , in which:

$$P_{IR} = k_h(W_w + W_s) \quad (11.6.5.1-1)$$

and where:

P_{AE} = dynamic lateral earth pressure force
 P_{IR} = horizontal inertial force due to seismic loading of the wall mass

C11.6.5.1

The estimation of seismic design forces should account for wall inertia forces in addition to the equivalent static forces. For semigravity walls in which the footing protrudes behind the back of the wall face (i.e., the heel), the weight of the soil located directly above the heel of the footing should be included in the calculated wall inertial force.

Where a wall supports a bridge structure, the seismic design forces should also include seismic forces transferred from the bridge through bearing supports which do not freely slide, e.g., elastomeric bearings in accordance with Article 14.6.3.

The static lateral earth pressure force acting behind the wall is already included in P_{AE} (i.e., P_{AE} is the combination of the static and seismic lateral earth pressure). See Article A11.3 for details on the calculation of P_{AE} . See Articles 3.11.6.3 and 11.10.10.1 for definitions of terms in Figure 11.6.5.1-1 not specifically defined in this Article.

Since P_{AE} is the combined lateral earth pressure force resulting from static earth pressure plus dynamic effects, the static earth pressure as calculated based on the lateral earth pressure coefficient, K_a , should not be added to the seismic earth pressure calculated in Article 11.6.5.3. The static lateral earth pressure coefficient, K_a , is, in effect, increased during seismic loading to K_{AE} (see Article 11.6.5.3) due to seismically induced inertial forces on the active wedge, and the potential increase in the volume of the active wedge itself due to flattening of the active failure surface. P_{AE} does not include any additional lateral forces caused by permanent surcharge loads located above the wall (e.g., the static force, F_p , and the dynamic force, $k_h W_{surcharge}$, in Figure 11.6.5.1-1, in which $W_{surcharge}$ is the weight of the surcharge). If the generalized limit equilibrium (GLE) method is used to calculate seismic lateral earth pressure on the wall, the effect of the surcharge on the total lateral force acting on the wall during seismic loading may, however, be taken directly into account when determining P_{AE} . Note that the inertial force due to the weight of the concentrated surcharge load, $k_h W_{surcharge}$, and the static force, F_p , are separate and both act

k_h = seismic horizontal acceleration coefficient
 W_w = the weight of the wall
 W_s = the weight of soil that is immediately above the wall, including the wall heel

To investigate the wall stability considering the combined effect of P_{AE} and P_{IR} and considering them not to be concurrent, the following two cases should be investigated:

- combine 100 percent of the seismic earth pressure, P_{AE} , with 50 percent of the wall inertial force, P_{IR} , and
- combine 50 percent of P_{AE} but no less than the static active earth pressure force (i.e., F_1 in Figure 11.10.5.2-1), with 100 percent of the wall inertial force, P_{IR} .

The most conservative result from these two analyses should be used for design of the wall. Alternatively, if approved by the Owner, more sophisticated numerical methods may be used to investigate nonconcurrency. For competent soils that do not lose strength under seismic loading, static strength parameters should be used for seismic design.

- For cohesive soils, total stress strength parameters based on undrained tests should be used during the seismic analysis.
- For clean cohesionless soils, the effective stress friction angle should be used.

For sensitive cohesive soils or saturated cohesionless soils, the potential for earthquake-induced strength loss shall be addressed in the analysis.

during seismic loading. They must therefore both be included in the seismic wall stability analysis. F_p is calculated as specified in Article 3.11.6.

For evaluating external stability of the wall and for evaluating safety against structural failure of the wall (internal stability), the simplest design approach that will ensure a safe result is to combine the total seismic earth pressure force with the inertial response of the wall section, assuming both are in phase. This approach is conservative in that the peak inertial response of the wall mass is not likely to occur at the same time as the peak seismic active pressure. Previous design practice, at least for MSE walls, has been to combine the full wall inertial force with only 50 percent of the dynamic increment of the total earth pressure (i.e., $P_{AE} - P_A$) to account for this lack of concurrence in the design forces.

Research using centrifuge testing of reduced scale walls by Al Atik and Sitar (2010) indicated that these two seismic forces are out of phase, in that when dynamic earth pressure was at its maximum, the wall inertial force was at its minimum and was very close to zero. When the wall inertial force was at its maximum, the total seismic earth pressure (i.e., P_{AE}) was close to its static value. They also indicated, however, that more coincidence between these two forces may still be possible for some wall configurations and ground motions. Nakamura (2006) made similar observations regarding lack of concurrence of these forces based on dynamic centrifuge testing he conducted. This research indicates that treating the two forces as nonconcurrent is justified in most cases.

See Al Atik and Sitar (2010) and Nakamura (2006) for examples of the application of numerical methods to investigate this issue of nonconcurrent forces.

The inertial force associated with the soil mass on the wall heel behind the retaining wall is not added to the active seismic earth pressure when structurally designing the retaining wall. The basis for excluding this inertial force is that movement of this soil mass is assumed to be in phase with the structural wall system with the inertial load transferred through the heel of the wall. Based on typical wave lengths associated with seismic loading, this is considered a reasonable assumption. However, the inertial force for the soil mass over the wall heel is included when determining the external stability of the wall.

Additional discussion and guidance on the selection of soil parameters for seismic design of walls and the potential consideration of soil cohesion are provided by Anderson et al. (2008).

Figure 11.6.5.1-1—Seismic Force Diagram for Gravity Wall External Stability Evaluation

11.6.5.2—Calculation of Seismic Acceleration Coefficients for Wall Design

11.6.5.2.1—Characterization of Acceleration at Wall Base

C11.6.5.2.1

The seismic horizontal acceleration coefficient, k_h , for computation of seismic lateral earth pressures and loads shall be determined on the basis of the A_s at the ground surface (i.e., $k_{h0} = A_s$, where k_{h0} is the seismic horizontal acceleration assuming zero wall displacement occurs). The acceleration coefficient determined at the original ground surface should be considered to be the acceleration coefficient acting at the wall base. For walls founded on Site Class A, B, or B/C soil (hard to soft rock), k_{h0} shall be based on 1.2 times A_s (i.e., $k_{h0} = 1.2 A_s$, with A_s determined for Site Class A or B, as applicable).

A_s is determined as specified in Article 3.10.

The seismic vertical acceleration coefficient, k_v , should be assumed to be zero for the purpose of calculating lateral earth pressures, unless the wall is significantly affected by near fault effects (see Article 3.10), or if relatively high vertical accelerations are likely to be acting concurrently with the horizontal acceleration.

In most situations, vertical and horizontal acceleration are at least partially out of phase. Therefore, k_v is usually rather small when k_h is near its maximum value. The typical assumption is to assume that k_v is zero for wall design.

11.6.5.2.2—Estimation of Acceleration Acting on Wall Mass

C11.6.5.2.2

The seismic lateral wall acceleration coefficient, k_h , shall be determined considering the effects of wave scattering or ground motion amplification within the wall and the ability of the wall to displace laterally. For wall heights less than 60.0 ft, simplified pseudostatic analyses

The Designer may use k_h for wall design without accounting for wave scattering and lateral deformation effects; however, various studies have shown that the ground motions in the mass of soil behind the wall will often be lower than k_{h0} at the ground surface, particularly

may be considered acceptable for use in determining the design wall mass acceleration. For wall heights greater than 60.0 ft, special dynamic soil structure interaction design analyses should be performed to assess the effect of spatially varying ground motions within and behind the wall and lateral deformations on the wall mass acceleration.

The height of the wall, H , shall be taken as the distance from the bottom of the heel of the retaining structure to the ground surface directly above the heel.

If the wall is free to move laterally under the influence of seismic loading and if lateral wall movement during the design seismic event is acceptable to the Owner, k_{h0} should be reduced to account for the allowed lateral wall deformation. The selection of a maximum acceptable lateral deformation should take into consideration the effect that deformation will have on the stability of the wall under consideration, the desired seismic performance level, and the effect that deformation could have on any facilities or structures supported by the wall. Where the wall is capable of displacements of 1.0 to 2.0 in. or more during the design seismic event, k_h may be reduced to $0.5k_{h0}$ without conducting a deformation analysis using the Newmark method (Newmark, 1965) or a simplified version of it. This reduction in k_h shall also be considered applicable to the investigation of overall stability of the wall and slope.

A Newmark sliding block analysis or a simplified form of that type of analysis should be used to estimate lateral deformation effects, unless the Owner approves the use of more sophisticated numerical analysis methods to establish the relationship between k_h and the wall displacement. Simplified Newmark analyses should only be used if the assumptions used to develop them are valid for the wall under consideration.

11.6.5.3—Calculation of Seismic Active Earth Pressures

Seismic active and passive earth pressures for gravity and semigravity retaining walls shall be determined following the methods described in this Article. Site conditions, soil and retaining wall geometry, and the earthquake ground motion determined for the site shall be considered when selecting the most appropriate method to use.

The seismic coefficient, k_h , used to calculate seismic earth pressures shall be the ground surface acceleration identified in Article 11.6.5.2.1 (i.e., A_s) after adjustments for 1) spectral or wave scattering effects and 2) limited amounts of permanent deformation as determined

for taller walls. However, in some cases, it is possible to have amplification of the ground motion in the wall relative to the wall base ground motion.

The desired performance of walls during a design seismic event can range from allowing limited damage to the wall or displacement of the wall to requiring damage-free, post-earthquake conditions. In many cases, a well-designed gravity or semigravity wall could slide several inches and perhaps even a foot or more, as well as tilt several degrees, without affecting the function of the wall or causing collapse, based on past performance of walls in earthquakes. However, the effect of such deformation on the facilities or structures located above, behind, or in front of the wall must also be considered when establishing an allowable displacement.

Work completed as part of NCHRP Report 611 (Anderson et al., 2008) concluded that, when using the Newmark method, the amount of permanent ground displacement associated with $k_h = 0.5k_{h0}$ will in most cases be less than 1.0 to 2.0 in. (i.e., use of $k_h = 0.5k_{h0}$ provides conservative results).

Details of specific simplified procedures that may be used to estimate wave scattering effects and lateral wall deformations to determine k_h are provided in Appendix A11. Those simplified procedures include Kavazanjian et al. (2011), Anderson et al. (2008), and Bray et al. (2009; 2010). Additional background needed to conduct a full Newmark sliding block analysis is also provided in Appendix A11.

The simplified, Newmark method-based equations mentioned previously present a relatively quick method of estimating the yield acceleration for a given maximum acceptable displacement or, alternatively, the displacements that will occur if the capacity to demand (C/D) ratio for a limiting equilibrium stability analysis is less than 1.0. Alternatively, two-dimensional numerical methods that allow seismic time history analyses may be used to estimate permanent displacements. Such models require considerable expertise in the set-up and interpretation of model results, particularly relative to the selection of strength parameters consistent with seismic loading. For this reason, use of this alternate approach should be adopted only with the Owner's concurrence.

C11.6.5.3

The suitability of the method used to determine active and passive earth seismic pressures should be determined after a review of features making up the static design, such as backfill soils and slope above the retaining wall. These conditions, along with the ground motion for a site, will affect the method selection.

The complete M–O equation is provided in Appendix A11. The M–O equation for seismic active earth pressure is based on the Coulomb earth pressure theory and is therefore limited to design of walls that have homogeneous, dry cohesionless backfill. The M–O equation has been shown to be most applicable when the

appropriate for the wall and anything the wall movement could affect (Article 11.6.5.2.2). The vertical acceleration coefficient, k_v , should be assumed to be zero for design as specified in Article 11.6.5.2.1.

For seismic active earth pressures, either the Mononobe–Okabe (M–O) Method or the GLE method should be used. For wall geometry or site conditions for which the M–O Method is not suitable, the GLE method should be used.

The M–O Method shall be considered acceptable for determination of seismic active earth pressures only where:

- the material behind the wall can be reasonably approximated as a uniform, cohesionless soil within a zone defined by a 3H:1V wedge from the heel of the wall,
- the backfill is not saturated and in a loose enough condition such that it can liquefy during shaking, and
- the combination of peak ground acceleration and backslope angle do not exceed the friction angle of the soil behind the wall, as specified in Eq. 11.6.5.3-1.

$$\phi \geq i + \theta_{MO} = i + \arctan\left(\frac{k_h}{1 - k_v}\right) \quad (11.6.5.3-1)$$

where:

- ϕ = the wall backfill friction angle
- i = backfill slope angle (degrees)
- k_h = the horizontal acceleration coefficient
- k_v = the vertical acceleration coefficient

Once K_{AE} is determined, the seismic active force, P_{AE} , shall be determined as:

$$P_{AE} = 0.5 \gamma h^2 K_{AE} \quad (11.6.5.3-2)$$

where:

- K_{AE} = seismic active earth pressure coefficient (dim)
- γ = the soil unit weight behind the wall (kips/ft³)
- h = the total wall height, including any soil surcharge present, at the back of the wall

The external active force computed from the GLE method, distributed over the wall height h , shall be used as the seismic earth pressure.

The equivalent pressure representing the total static and seismic active force (P_{AE}) as calculated by either method should be distributed using the same distribution as the static earth pressure used to design the wall when used for external stability evaluations, as illustrated in Figure 11.6.5.1-1, but no less than $H/3$. For the case when a sloping soil surcharge is present behind the wall face (h in Figure 11.6.5.1-1), this force shall be distributed over the total height, h .

For complex wall systems or complex site conditions, with the owner's approval, dynamic

backfill is homogenous and can be characterized as cohesionless.

Another important limitation of the M–O equation is that there are combinations of acceleration and slope angle in which real solutions to the equation are no longer possible or that result in values that rapidly approach infinity. The contents of the radical in this equation must be positive for a real solution to be possible. In past practice, when the combination of acceleration and slope angle results in a negative number within the radical in the equation, rather than allowing that quantity to become negative, it was artificially set at zero. While this practice made it possible to get a value of K_{AE} , it also tended to produce excessively conservative results. Therefore, in such cases it is better to use an alternative method.

For many situations, gravity and semigravity walls are constructed by cutting into an existing slope where the soil properties differ from the backfill that is used behind the retaining wall. In situations where soil conditions are not homogeneous and the failure surface is flatter than the native slope, seismic active earth pressures computed for the M–O equation using the backfill properties may no longer be valid, particularly if there is a significant difference in properties between the native and backfill soils.

However, the M–O Method has been used in past design practice for estimating seismic earth pressures for many of these situations due to lack of an available alternative. Various approaches to force the method to be usable for such situations have been used, such as estimating some type of average soil property for layered soil conditions or limiting the acceleration to prevent the radical in the equation from being negative, among others. With the exception of seismic passive pressure estimation, this practice has typically resulted in excessively conservative designs and it is not recommended to continue this practice.

The GLE method consists of conducting a seismic slope stability analysis in which k_h is used as the acceleration coefficient, typically using a computer program in which the applied force necessary to maintain equilibrium (i.e., a capacity/demand ratio of 1.0) under seismic loading is determined. This force is P_{AE} . Specific procedures used to conduct this method are provided in Appendix A11. The GLE method should be used when the M–O Method is not suitable due to the wall geometry, seismic acceleration level, or site conditions.

The Coulomb Wedge Equilibrium Method, also referred to as the trial wedge method, as described in Peck et al. (1974) and California Department of Transportation (Caltrans) (2010), may also be used for situations when the M–O Method is not suitable but a hand calculation method is desired, provided that the soil conditions are not too complex (e.g., layered soil conditions behind the

numerical soil structure interaction (SSI) methods should also be considered.

wall). Other than the potential ability to use the trial wedge method as a hand calculation method, it has no real advantages over the GLE method.

Studies have indicated that classic limit equilibrium based methods such as the M–O, GLE, and the Coulomb Wedge Equilibrium methods may be overly conservative even if the limitations listed above are considered. See Bray et al. (2010) and Lew et al. (2010a, 2010b) with regard to the generation of seismic earth pressures behind walls and the applicability of the M–O or similar methods.

For cases in which the wall seismic design result appears to be excessively conservative relative to past experience in earthquakes, other than taking advantage of the no seismic analysis provisions in Article 11.5.4.2, there are no simple solutions; numerical dynamic soil–structure interaction (SSI) modeling may need to be considered. See Bray et al. (2010) for an example. Dynamic numerical SSI solutions may also be needed for more complex wall systems and for walls in which the seismic loading is severe. Due to the complexities of such analyses, an independent peer review of the analysis and results is recommended.

Past practice for locating the resultant of the static and seismic earth pressure for external wall stability has been to either assume a uniform distribution of lateral earth pressure for the combined static plus seismic stress or, if the static and seismic components of earth pressure are treated separately, using an inverted trapezoid for the seismic component, with the seismic force located at $0.6h$ above the wall base, and combining that force with the normal static earth pressure distribution (Seed and Whitman, 1970). More recent research indicates the location of the resultant of the total earth pressure (static plus seismic) should be located at $h/3$ above the wall base (Clough and Fragaszy, 1977) (Al Atik and Sitar, 2010) (Bray et al., 2010) (Lew et al., 2010a, 2010b). See Appendix A11 for additional discussion on this issue. As a minimum, the combined resultant of the active and seismic earth pressure, i.e., P_{AE} , should be located no lower, relative to the wall base, than the static earth pressure resultant. However, a slightly higher combined static/seismic resultant location (e.g., $0.4h$ to $0.5h$) may be considered, since there is limited evidence the resultant could be higher, especially for walls in which the impact of failure is relatively high.

Most natural cohesionless soils have some fines content that contributes cohesion, particularly for short-term loading conditions. Similarly, cohesionless backfills are rarely fully saturated and partial saturation provides for some apparent cohesion, even for most clean sands. The effects of cohesion, whether actual or apparent, are an important issue to be considered in practical design problems.

The M–O equation has been extended to c - ϕ soils by Prakash and Saran (1966), where solutions were obtained for cases including the effect of tension cracks and wall adhesion. Similar solutions are also discussed by Richards and Shi (1994) and Chen and Liu (1990).

Results of analyses by Anderson et al. (2008) show a significant reduction in the seismic active pressure for small values of cohesion. From a design perspective, this means that even a small amount of cohesion in the soil could reduce the demand required for retaining wall design.

From a design perspective, the uncertainties in the amount of cohesion or apparent cohesion make it difficult to explicitly incorporate the contributions of cohesion in many situations, particularly in cases where clean backfill materials are being used, regardless of the potential benefits of apparent cohesion that could occur if the soil is partially saturated. Realizing these uncertainties, the following guidelines are suggested.

- Where cohesive soils are being used for backfill or where native soils have a clear cohesive strength component, the designer should give consideration to incorporating some effects of cohesion in the determination of the seismic coefficient.
- If the cohesion in the soil behind the wall results primarily from capillarity stresses, especially in relatively low fines content soils, it is recommended that cohesion be neglected when estimating seismic earth pressure.

The groundwater within the active wedge or submerged conditions (e.g., as in the case of a retaining structure in a harbor or next to a lake or river) can influence the magnitude of the seismic active earth pressure. The time-averaged mean groundwater elevation should be used when assessing groundwater effects.

If the soil within the wedge is fully saturated, then the total unit weight, γ_t , should be used to estimate the earth pressure when using the M–O Method, under the assumption that the soil and water move as a unit during seismic loading. This situation will apply for soils that are not free draining.

If the backfill material is a very open granular material, such as quarry spalls, it is possible that the water will not move with the soil during seismic loading. In this case, the effective unit weight should be used in the pressure determination and an additional force component due to hydrodynamic effects should be added to the wall pressure. Various methods are available to estimate the hydrodynamic pressure; see Kramer (1996). Generally, these methods involve a form of the Westergaard solution.

11.6.5.4—Calculation of Seismic Earth Pressure for Nonyielding Abutments and Walls

For abutment walls and other walls that are considered nonyielding, the value of k_h used to calculate seismic earth pressure shall be increased to $1.0k_{h0}$, unless the Owner approves the use of more sophisticated numerical analysis techniques to determine the seismically induced earth pressure acting on the wall,

C11.6.5.4

The lateral earth pressure calculation methodologies provided in Article 11.6.5.3 assume that the abutment or wall is free to laterally yield a sufficient amount to mobilize peak soil strengths in the backfill. Examples of walls that may be nonyielding are integral abutments, abutment walls with structural wing walls, tunnel

considering the ability of the wall to yield in response to lateral loading. In this case, k_h should not be corrected for wall displacement, since displacement is assumed to be zero. However, k_h should be corrected for wave scattering effects as specified in Article 11.6.5.2.2.

portal walls, and tied back cylinder pile walls. For granular soils, peak soil strengths can be assumed to be mobilized if deflections at the wall top are about 0.5 percent of the abutment or wall height. For walls restrained from movement by structures, batter piles, or anchors, lateral forces induced by backfill inertial forces could be greater than those calculated by M–O or GLE methods of analysis. Simplified elastic solutions presented by Wood (1973) for rigid nonyielding walls also indicate that pressures are greater than those given by M–O and GLE analysis. These solutions also indicate that a higher resultant location for the combined effect of static and seismic earth pressure of $h/2$ may be warranted for nonyielding abutments and walls and should be considered for design. The use of a factor of 1.0 applied to k_{h0} is recommended for design where doubt exists that an abutment or wall can yield sufficiently to mobilize backfill soil strengths. In general, if the lack of ability of the wall to yield requires that the wall be designed for K_0 conditions for the strength limit state, then a k_h of $1.0k_{h0}$ should be used for seismic design.

Alternatively, numerical methods may be used to better quantify the yielding or nonyielding nature of the wall and its effect on the seismic earth pressures that develop, if approved by the Owner.

11.6.5.5—Calculation of Seismic Passive Earth Pressure

For estimating seismic passive earth pressures, wall friction and the deformation required to mobilize the passive resistance shall be considered and a log spiral design methodology shall be used. The M–O Method shall not be used for estimating passive seismic earth pressure.

Seismic passive earth pressures shall be estimated using procedures that account for the friction between the retaining wall and the soil, the nonlinear failure surface that develops in the soil during passive pressure loading, and for wall embedment greater than or equal to 5.0 ft, the inertial forces in the passive pressure zone in front of the wall from the earthquake. For wall embedment depths less than 5.0 ft, passive pressure should be calculated using the static methods provided in Section 3.

In the absence of any specific guidance or research results for seismic loading, a wall interface friction equal to two-thirds of the soil friction angle should be used when calculating seismic passive pressures.

C11.6.5.5

The seismic passive earth pressure becomes important for walls that develop resistance to sliding from the embedded portion of the wall. For these designs, it is important to estimate passive pressures that are not overly conservative or unconservative for the seismic loading condition. This is particularly the case if displacement-based design methods are used but it can also affect the efficiency of designs based on limit-equilibrium methods.

If the depth of embedment of the retaining wall is less than 5.0 ft, the passive pressure can be estimated using static methods given in Section 3 of these Specifications. For this depth of embedment, the inertial effects from earthquake loading on the development of passive pressures will be small.

For greater depths of embedment, the inertial effects of ground shaking on the development of passive pressures should be considered. This passive zone typically extends three to five times the embedment depth beyond the face of the embedded wall.

Shamsabadi et al. (2007) have developed a methodology for estimating the seismic passive pressures while accounting for wall friction and the nonlinear failure surface within the soil. Appendix A11 provides charts based on this development for a wall friction of two-thirds of the soil friction angle and a range of seismic coefficients and soil properties (i.e., soil friction angles and soil cohesion values).

The seismic coefficient used in the passive seismic earth pressure calculation is the same value as used for the seismic active earth pressure calculation. Wave

scattering reductions are also appropriate to account for incoherency of ground motions in the soil if the depth of the passive zone exceeds 20.0 ft. For most wall designs, the difference between the seismic coefficient behind the wall relative to seismic coefficient of the soil in front of the wall is too small to warrant use of different values.

The M–O equation for seismic passive earth pressure is not recommended for use in determining the seismic passive pressure, despite its apparent simplicity. For passive earth pressure determination, the M–O equation is based on the Coulomb method of determining passive earth pressure; this method can overestimate the earth pressure in some cases.

A key consideration during the determination of static and seismic passive pressures is the wall friction. Common practice is to assume that some wall friction will occur for static loading. The amount of interface friction for static loading is often assumed to range from 50 percent to 80 percent of the soil friction angle. Similar guidance is not available for seismic loading.

Another important consideration when using the seismic passive earth pressure is the amount of deformation required to mobilize this force. The deformation to mobilize the passive earth pressure during static loading is usually assumed to be large—typically 2 percent to 6 percent of the embedded wall height. Similar guidance is not available for seismic loading and therefore the normal approach during design for seismic passive earth pressures is to assume that the displacement to mobilize the seismic passive earth pressure is the same as for static loading.

11.6.5.6—Wall Details for Improved Seismic Performance

Details that should be addressed for gravity and semigravity walls in seismically active areas, defined as Seismic Zone 2 or higher, or a peak ground acceleration A_s greater than 0.15g, include the following:

- *Vertical Slip Joints, Expansion Joints, and Vertical Joints between an Abutment Curtain Wall and the Freestanding Wall:* Design to prevent joint from opening up and allowing wall backfill to flow through the open joint without sacrificing the joint's ability to slip to allow differential vertical movement. This also applies to joints at wall corners. Compressible joint fillers, bearing pads, and sealants should be used to minimize damage to facing units due to shaking. The joint should also be designed in a way that allows a minimum amount of relative movement between the adjacent facing units to prevent stress build up between facing units during shaking (Extreme Event I), as well as due to differential deformation between adjacent wall sections at the joint for the service and strength limit states.

C11.6.5.6

These recommended details are based on previous experiences with walls in earthquakes (e.g., Yen et al., 2011). Walls that did not utilize these details tended to have a higher frequency of problems than walls that did utilize these details.

With regard to preventing joints from opening up during shaking, this can be addressed through use of a backup panel placed behind the joint, a slip joint cover placed in front of the joint, or the placement of the geotextile strip behind the facing panels to bridge across the joint. The special units should allow differential vertical movement between facing units to occur while maintaining the functionality of the joint. The amount of overlap between these joint elements and the adjacent facing units is determined based on the amount of relative movement between facing units that is anticipated in much the same way that the bridge seat width is determined for bridges.

Little guidance on the amount of overlap between the backing panel and the facing panels is available for walls but past practice has been to provide a minimum overlap of 2.0 to 4.0 in. A geotextile strip may also be placed between the backfill soil and the joint or joint and backing

- *Coping at Wall Top:* Should be used to prevent toppling of top facing units and excessive differential lateral movement of the facing.
- *Wall Backfill Stability:* Backfill should be well graded and angular enough to interlock/bind together well to minimize risk of fill spilling through open wall joints.
- *Wall Backfill Silt and Clay Content:* Wall backfills classified as a silt or clay should in general not be used in seismically active areas.
- *Structures and Foundations within the Wall Active Zone:* The effect of these structures and foundations on the wall seismic loading shall be evaluated and the wall designed to take the additional load.
- *Protrusions through the Wall Face:* The additional seismic force transmitted to the wall, especially the facing, through the protruding structure (e.g., a culvert or drainage pipe) shall be evaluated. The effect of differential deformation between the protrusion and the wall face shall also be considered. Forces transmitted to the wall face by the protruding structure should be reduced through the use of compressible joint filler or bearing pads and sealant.

panel combination. Typical practice has been to use a minimum overlap of the geotextile beyond the edges of the joint of 6.0 to 9.0 in. and the geotextile is usually attached to the back of the panel using adhesive. Typically, a Class 1 or Class 2 high elongation (>50 percent strain at peak strength) drainage geotextile in accordance with AASHTO M 288 is used. Similarly, this technique may be applied to the joint between the facing units and protrusions through the wall facing.

For wall corners, not cast monolithically, a special facing unit formed to go across the corner should be used to provide continuity and stability across a continuous corner vertical joint. Historically, corners and abrupt alignment changes in walls have had a higher incidence of performance problems during earthquakes than relatively straight sections of the wall alignment, as the corners may become damaged and separate. This should be considered when designing and detailing a wall corner for seismic loading. Careful attention should be undertaken in the placement and compaction of the fill near wall corners since the more difficult access can cause the fill not to be compacted to its optimum density, potentially causing increased deformations at the corners during a seismic event.

Note that the corner or abrupt alignment change enclosed angle as defined in the previous paragraph can either be internal or external to the wall.

With regard to wall backfill materials, walls that have used compacted backfills with high silt or clay content have historically exhibited more performance problems during earthquakes than those that have utilized compacted granular backfills. This has especially been an issue if the wall backfill does not have adequate drainage features to keep water out of the backfill and the backfill fully drained. Also, very uniform clean sand backfill, especially if it lacks angularity, has also been problematic with regard to wall seismic performance. The issue is how well it can be compacted and remain in a compacted state. A backfill soil coefficient of uniformity of greater than 4 is recommended and, in general, the backfill particles should be classified as subangular or angular rather than rounded or subrounded. The less angular the backfill particles, the more well graded the backfill material needs to be.

For additional information on good wall details, see Berg et al. (2009). While this reference is focused on MSE wall details, similar details could be adapted for gravity and semigravity walls.

11.6.6—Drainage

Backfills behind abutments and retaining walls shall be drained or, if drainage cannot be provided, the abutment or wall shall be designed for loads due to earth pressure, plus full hydrostatic pressure due to water in the backfill.

C11.6.6

Weep holes or geocomposite panel drains at the wall face do not assure fully drained conditions. Drainage systems should be designed to completely drain the entire retained soil volume behind the retaining wall face.

11.7—PIERS

11.7.1—Load Effects in Piers

Piers shall be designed to transmit the loads on the superstructure, and the loads acting on the pier itself, onto the foundation. The loads and load combinations shall be as specified in Section 3.

The structural design of piers shall be in accordance with the provisions of Sections 5, 6, 7, and 8, as appropriate.

11.7.2—Pier Protection

11.7.2.1—Collision

Where the possibility of collision exists from highway or river traffic, an appropriate risk analysis should be made to determine the degree of impact resistance to be provided and/or the appropriate protection system. Collision loads shall be determined as specified in Articles 3.6.5 and 3.14.

11.7.2.2—Collision Walls

Collision walls may be required by railroad owners if the pier is in close proximity to the railroad.

C11.7.2.2

Collision walls are usually required by the railroad owner if the column is within 25.0 ft of the rail. Some railroad owners require a collision wall 6.5 ft above the top of the rail between columns for railroad overpasses.

11.7.2.3—Scour

The scour potential shall be determined and the design shall be developed to prevent failure from this condition as specified in Articles 2.6.4.4.3 and 2.6.4.5.

11.7.2.4—Facing

Where appropriate, the pier nose should be designed to effectively break up or deflect floating ice or drift.

C11.7.2.4

In these situations, pier life can be extended by facing the nosing with steel plates or angles, and by facing the pier with granite.

11.8—NONGRAVITY CANTILEVERED WALLS

11.8.1—General

Nongravity cantilevered walls may be considered for temporary and permanent support of stable and unstable soil and rock masses. The feasibility of using a nongravity cantilevered wall at a particular location shall be based on the suitability of soil and rock conditions within the depth of vertical element embedment to support the wall.

C11.8.1

Depending on soil conditions, nongravity cantilevered walls less than about 15.0 ft in height are usually feasible, with the exception of cylinder or tangent pile walls, where greater heights can be used.

11.8.2—Loading

The provisions of Article 11.6.1.2 shall apply. The load factor for lateral earth pressure, EH , shall be applied to the lateral earth pressures for the design of nongravity cantilevered walls.

11.8.3—Movement at the Service Limit State**11.8.3.1—Movement**

The provisions of Articles 10.7.2.2 and 10.8.2.1 shall apply. The effects of wall movements on adjacent facilities shall be considered in the selection of the design earth pressures in accordance with the provisions of Article 3.11.1.

11.8.4—Safety against Soil Failure at the Strength Limit State**11.8.4.1—Overall Stability**

The provisions of Article 11.6.3.7 shall apply.

The provisions of Article 11.6.3.5 shall apply.

Vertical elements shall be designed to support the full design earth, surcharge, and water pressures between the elements. In determining the embedment depth to mobilize passive resistance, consideration shall be given to planes of weakness, e.g., slickensides, bedding planes, and joint sets that could reduce the strength of the soil or rock determined by field or laboratory tests. Embedment in intact rock, including massive to appreciably jointed rock which should not fail through a joint surface, shall be based on the shear strength of the rock mass.

C11.8.2

Lateral earth pressure distributions for design of nongravity cantilevered walls are provided in Article 3.11.5.6.

C11.8.3.1

Table C3.11.1-1 provides approximate magnitudes of relative movements required to achieve active earth pressure conditions in the retained soil and passive earth pressure conditions in the resisting soil.

C11.8.4.1

Discrete vertical elements penetrating across deep failure planes can provide resistance against failure. The magnitude of resistance will depend on the size, type, and spacing of vertical elements. Use of vertical wall elements to provide resistance against overall stability failure is described in Article C11.9.4.4.

The maximum spacing between vertical supporting elements depends on the relative stiffness of the vertical elements. Spans of 6.0 to 10.0 ft are typical, depending on the type and size of facing.

In determining the embedment depth of vertical wall elements, consideration should be given to the presence of planes of weakness in the soil or rock that could result in a reduction of passive resistance. For laminated, jointed, or fractured soils and rocks, the residual strength along planes of weakness should be considered in the design and, where the planes are oriented at other than an angle of $(45 \text{ degrees} - \phi'_r/2)$ from the horizontal in soil or 45 degrees from the horizontal in rock toward the excavation, the orientation of the planes should also be considered. Where the wall is located on a bench above a deeper excavation, consideration should be given to the potential for bearing failure of a supporting wedge of soil or rock through intact materials along planes of weakness.

In designing permanent nongravity cantilevered walls with continuous vertical elements embedded in granular soil, the simplified earth pressure distributions in Figure 3.11.5.6-3 may be used with the following simplified design procedure (Teng, 1962):

- Determine the magnitude of lateral pressure on the wall due to earth pressure, surcharge loads, and differential water pressure over the design height of the wall using k_{a1} .
- Determine the magnitude of lateral pressure on the wall due to earth pressure, surcharge loads, and differential water pressure over the design height of the wall using k_{a2} .

- Determine in the following equation the value x as defined in Figure 3.11.5.6-3 to determine the distribution of net passive pressure in front of the wall below the design height:

$$x = [\gamma k_{a2} \gamma'_1 H] / [(\phi k_{p2} - \gamma k_{a2}) \gamma'_2] \quad (\text{C11.8.4.1-1})$$

where:

- γ = load factor for horizontal earth pressure, EH (dim.)
- k_{a2} = the active earth pressure coefficient for soil 2 (dim.)
- γ'_1 = the effective soil unit weight for soil 1 (kef)
- H = the design height of the wall (ft)
- ϕ = the resistance factor for passive resistance in front of the wall (dim.)
- k_{p2} = the passive earth pressure coefficient for soil 2 (dim.)
- γ'_2 = the effective soil unit weight for soil 2 (kef)

- Sum moments about the point of action of F (the base of the wall) to determine the embedment, D_o , for which the net passive pressure is sufficient to provide moment equilibrium.
- Determine the depth at which the shear in the wall is zero, i.e., the point at which the areas of the driving and resisting pressure diagrams are equivalent.
- Calculate the maximum bending moment at the point of zero shear.
- Calculate the design depth, $D = 1.2D_o$, to account for errors inherent in the simplified passive pressure distribution.

For design of temporary, nongravity cantilevered walls with continuous vertical elements embedded in cohesive soil, an approach similar to the simplified method for continuous vertical elements embedded in granular soil may be applied considering the earth pressure distributions shown in Figures 3.11.5.6-6 and 3.11.5.6-7 (Teng, 1962).

11.8.5—Safety against Structural Failure

11.8.5.1—Vertical Wall Elements

Vertical wall elements shall be designed to resist all horizontal earth pressure, surcharge, water pressure, and earthquake loadings.

C11.8.5.1

Discrete vertical wall elements include driven piles, drilled shafts, and auger-cast piles, e.g., piles and built-up sections installed in preaugered holes.

Continuous vertical wall elements are continuous throughout both their length and width, although vertical joints may prevent shear and/or moment transfer between adjacent sections. Continuous vertical wall elements include sheet piles, precast or cast-in-place concrete diaphragm wall panels, tangent-piles, and tangent drilled shafts.

11.8.5.2—Facing

The maximum spacing between discrete vertical wall elements shall be determined based on the relative stiffness of the vertical elements and facing, the type and condition of soil to be supported, and the type and condition of the soil in which the vertical wall elements are embedded. Facing may be designed assuming simple support between elements, with or without soil arching, or assuming continuous support over several elements.

If timber facing is used, it shall be stress-grade pressure-treated lumber in conformance with Section 8. If timber is used where conditions are favorable for the growth of decay-producing organisms, wood should be pressure-treated with a wood preservative unless the heartwood of a naturally decay-resistant species is available and is considered adequate with respect to the decay hazard and expected service life of the structure.

The maximum bending moments and shears in vertical wall elements may be determined using the loading diagrams in Article 3.11.5.6, and appropriate load and resistance factors.

C11.8.5.2

In lieu of other suitable methods, for preliminary design the maximum bending moments in facing may be determined as follows:

- For simple spans without soil arching:

$$M_{max} = 0.125 pL^2 \quad (C11.8.5.2-1)$$

- For simple spans with soil arching:

$$M_{max} = 0.083 pL^2 \quad (C11.8.5.2-2)$$

- For continuous spans without soil arching:

$$M_{max} = 0.1 pL^2 \quad (C11.8.5.2-3)$$

- For continuous spans with soil arching:

$$M_{max} = 0.083 pL^2 \quad (C11.8.5.2-4)$$

where:

- M_{max} = factored flexural moment on a unit width or height of facing (kip-ft/ft)
- p = average factored lateral pressure, including earth, surcharge, and water pressure acting on the section of facing being considered (ksf/ft)
- L = spacing between vertical elements or other facing supports (ft)

If the variations in lateral pressure with depth are large, moment diagrams should be constructed to provide more accuracy. The facing design may be varied with depth.

Eq. C11.8.5.2-1 is applicable for simply supported facing behind which the soil will not arch between vertical supports, e.g., in soft cohesive soils or for rigid concrete facing placed tightly against the in-place soil. Eq. C11.8.5.2-2 is applicable for simply supported facing behind which the soil will arch between vertical supports, e.g., in granular or stiff cohesive soils with flexible facing or rigid facing behind which there is sufficient space to permit the in-place soil to arch. Eqs. C11.8.5.2-3 and C11.8.5.2-4 are applicable for facing which is continuous over several vertical supports, e.g., reinforced shotcrete or concrete.

11.8.6—Seismic Design of Nongravity Cantilever Walls

11.8.6.1—General

The effect of earthquake loading shall be investigated using the Extreme Event I limit state of Table 3.4.1-1 with resistance factor, $\phi = 1.0$, a load factor, $\gamma_p = 1.0$ and an accepted methodology, with the exception of overall stability of the wall, in which case a resistance factor of 0.9 and a load factor, $\gamma_p = 1.0$ should be used as specified in Articles 3.4.1 and 11.5.8.

The seismic analysis of the nongravity cantilever retaining wall shall demonstrate that the cantilever wall will maintain overall stability and withstand the seismic earth pressures induced by the design earthquake without excessive structural moments and shear on the cantilever wall section. Limit equilibrium methods or numerical displacement analyses shall be used to confirm acceptable wall performance.

Design checks should also be performed for failures below the excavation level but through the structure. These analyses should include the contributions of the structural section to slope stability. If the structural contribution to resistance is being accounted for in the stability assessment, the moments and shears developed by the structural section should be checked to confirm that specified structural limits are not exceeded.

11.8.6.2—Seismic Active Lateral Earth Pressure

Lateral earth pressures and inertial forces for seismic design of nongravity cantilever walls shall be determined as specified in Article 11.6.5. The resulting active seismic earth pressure shall be distributed as specified in Article 11.6.5.3, above the excavation level as shown in Figure 11.8.6.2-1.

To reduce the lateral seismic acceleration coefficient, k_{h0} , for the effects of horizontal wall displacement in accordance with Article 11.6.5.2.2, analyses shall demonstrate that the displacements associated with the yield acceleration do not result in any of the following:

C11.8.6.1

During seismic loading, the nongravity cantilever wall develops resistance to load through the passive resistance of the soil below the excavation depth. The stiffness of the structural wall section above the excavation depth must be sufficient to transfer seismic forces from the soil behind the wall, through the structural section, to the soil below. The seismic evaluation of the nongravity cantilever wall requires, therefore, determination of the demand on the wall from the seismic active earth pressure and the capacity of the soil from the seismic passive soil resistance.

For flexible cantilevered walls, forces resulting from wall inertia effects may be ignored in estimating the seismic design forces. However, for very massive nongravity cantilever wall systems, such as tangent or secant pile walls, wall mass inertia effects should be included in the seismic analysis of the wall.

Two types of stability checks are conducted for the nongravity cantilever wall: global stability and internal stability. In contrast to gravity and semigravity walls, sliding, overturning, and bearing stability are not design considerations for this wall type. By sizing the wall to meet earth pressures, the equilibrium requirements for external stability are also satisfied.

The global stability check for seismic loading involves a general slope failure analysis that extends below the base of the wall. Typically, the embedment depth of the wall is 1.5 to 2 times the wall height above the excavation level. For these depths, global stability is not normally a concern, except where soft layers are present below the toe of the wall.

The global stability analysis is performed with a slope stability program. The failure surfaces used in the analysis should normally extend below the depth of the structure member.

Internal stability for a nongravity cantilever wall refers to the moments and shear forces developed in the wall from the seismic loads.

C11.8.6.2

In most situations, the nongravity cantilever wall moves enough during seismic loading to develop seismic active earth pressures; however, the amount of movement may not be the 1.0 to 2.0 in. necessary to allow reduction in the seismic coefficient by 50 percent, unless analyses demonstrate that permanent wall movements will occur without damaging the wall components. Beam-column analyses involving p - y modeling of the vertical wall elements will usually be required to make this assessment.

If the effect of cohesion in reducing the seismic active earth pressure acting on the wall is considered,

- Yield of structural members making up the wall, such as with a pile-supported wall;
- Loads applied to the lateral support systems (e.g., ground anchors in anchored wall systems; see Article 11.9.6) that exceed the available factored resistance; and
- Unacceptable deformation or damage to any facilities located in the vicinity of the wall.

the reduction in earth pressure due to cohesion should not be combined with a reduction in earth pressure due to horizontal wall displacement.

As described in Article 11.6.5.3, an alternate approach for determining the seismic active earth pressure involves use of the GLE method. If used for the design of a nongravity cantilever wall, the geometry of the slope stability model should extend from the ground surface to the bottom or toe of the sheet pile or other nongravity cantilever walls in which the wall is continuous both above and below the excavation line in front of the wall. For soldier pile walls, the analysis extends to the excavation level. The seismic active pressure is determined as described in Appendix A11.

The static lateral earth pressure force acting behind the wall is already included in P_{AE} (i.e., P_{AE} is the combination of the static and seismic lateral earth pressure). See Articles 3.11.6.3 and 11.10.10.1 for definition of terms in Figure 11.8.6.2-1 not specifically defined in this Article.

Figure 11.8.6.2-1—Seismic Force Diagram for Nongravity Cantilever Wall External Stability Evaluation

11.8.6.3—Seismic Passive Lateral Earth Pressure

The method used to compute the seismic passive pressure shall consider wall interface friction, the nonlinear failure surface that develops during passive pressure loading, and the inertial response of the soil within the passive pressure wedge for depths greater than 5.0 ft. Cohesion and frictional properties of the soil shall be included in the determination. Passive pressure under seismic loading shall be determined as specified in Article 11.6.5.5.

In the absence of any specific guidance or research results for seismic loading, a wall interface friction equal to two-thirds of the soil friction angle should be used when calculating seismic passive pressures.

The seismic passive pressure shall be applied as a triangular pressure distribution similar to that for static loading. The amount of displacement to mobilize the passive pressure shall also be considered in the analyses.

The peak seismic passive pressure should be based on:

- the time-averaged mean groundwater elevation,
- the full depth of the below-ground structural element, not neglecting the upper 2.0 ft of soil as typically done for static analyses,
- the strength of the soil for undrained loading, and
- the wall friction in the passive pressure estimate taken as two-thirds times the soil strength parameters from a total stress analysis.

In the absence of specific guidance for seismic loading, a reduction factor of 0.67 should be applied to the seismic passive pressure during the seismic check to limit displacement required to mobilize the passive earth pressure.

C11.8.6.3

The effects of live loads are usually neglected in the computation of seismic passive pressure.

Reductions in the seismic passive earth pressure may be warranted to limit the amount of deformation required to mobilize the seismic passive earth pressure, if a limit equilibrium method of analysis is used, to make sure that the wall movement does not result in the collapse of the wall or of structures directly supported by the wall. However, a passive resistance reduction factor near 1.0 may be considered if, in the judgment of the engineer, such deformations to mobilize the passive resistance would not result in wall or supported structure collapse.

If the nongravity cantilever wall uses soldier piles to develop reaction to active pressures, adjustments must be made in the passive earth pressure determination to account for the three-dimensional effects below the excavation level as soil reactions are developed. In the absence of specific seismic studies dealing with this issue, it is suggested that methods used for static loading be adopted. One such method, documented in the Caltrans *Shoring Manual* (2010), suggests that soldier piles located closer than three pile diameters be treated as a continuous wall. For soldier piles spaced at greater distances, the approach in the *Shoring Manual* depends on the type of soil:

- For cohesive soils, the effective pile width that accounts for arching ranges from one pile diameter for very soft soil to two diameters for stiff soils.
- For cohesionless soils, the effective width is defined as $0.08\phi B$ up to three pile diameters. In this relationship, ϕ is the soil friction angle and B is the soldier pile width.

During seismic loading, the inertial response of the soil within the passive pressure failure wedge will decrease the soil resistance during a portion of each loading cycle. Figures provided in Appendix A11 can be used to estimate the passive soil resistance for different friction values and normalized values of cohesion. A preferred methodology for computing seismic earth pressures with consideration of wall friction, nonlinear soil failure surface, and inertial effects involves use of the procedures documented by Shamsabadi et al. (2007).

11.8.6.4—Wall Displacement Analyses to Determine Earth Pressures

Numerical displacement analyses, if used, shall show that moments, shear forces, and structural displacements resulting from the peak ground surface accelerations are within acceptable levels. These analyses shall be conducted using a model of the wall system that includes the structural stiffness of the wall section, as well as the load displacement response of the soil above and below the excavation level.

C11.8.6.4

Numerical displacement methods offer a more accurate and preferred method of determining the response of nongravity cantilever walls during seismic loading. Either of two numerical approaches can be used. One involves a simple beam-column approach; the second involves the use of a two-dimensional computer model. Both approaches need to appropriately represent the load displacement behavior of the soil and the structural members during loading. For soils, this includes nonlinear stress-strain effects; for structural members, consideration must be given to ductility of the structure, including the use of cracked versus uncracked section properties if concrete structures are being used.

Beam-Column Approach

The pseudostatic seismic response of a nongravity cantilever wall can be determined by representing the wall in a beam-column model with the soil characterized by p - y springs. This approach is available with commercially available computer software. The total seismic active pressure above the excavation level is used for wall loading. Procedures given in Article 11.8.6.2 should be used to make this estimate.

For this approach, the p - y curves below the excavation level need to be specified. For discrete structural elements (e.g., soldier piles), conventional p - y curves for piles may be used. For continuous walls or walls with pile elements at closer than 3-diameter spacing, p - and y -modifiers have been developed by Anderson et al. (2008) to represent a continuous (sheet pile or secant pile) retaining wall. The procedure involves:

- Developing conventional isolated pile p - y curves using a 4.0-ft diameter pile following API (1993) procedures for sands or clays.
- Normalizing the isolated p - y curves by dividing the p values by 4.0 ft.
- Applying the following p - and y -multipliers, depending on the type of soil, in a conventional beam-column analysis.

Soil Type	p -multiplier	y -multiplier
Sand	0.5	4.0
Clay	1.0	4.0

It should be noted that the starting point of using a 4.0 ft diameter pile has nothing to do with the actual diameter of the vertical elements in the wall. It is simply a starting point in the procedure to obtain p - y curves that are applicable to a wall. The p - y curves obtained in the final step of this process are intended to be applicable to a continuous wall.

Supporting information for the development and use of the p - y approach identified above is presented in Volume 1 of

drainage control measures should be evaluated by seepage analyses.

11.9—ANCHORED WALLS

11.9.1—General

Anchored walls, whose elements may be proprietary, employ grouted in anchor elements, vertical wall elements, and facing. Anchored walls, illustrated in Figure 11.9.1-1, may be considered for both temporary and permanent support of stable and unstable soil and rock masses.

The feasibility of using an anchored wall at a particular location should be based on the suitability of subsurface soil and rock conditions within the bonded anchor stressing zone.

Where fill is placed behind a wall, either around or above the unbonded length, special designs and construction specifications shall be provided to prevent anchor damage.

Figure 11.9.1-1—Anchored Wall Nomenclature and Anchor Embedment Guidelines

11.9.2—Loading

The provisions of Article 11.6.1.2 shall apply, except that shrinkage and temperature effects need not be considered.

11.9.3—Movement at the Service Limit State

11.9.3.1—Movement

The provisions of Articles 10.6.2.2, 10.7.2.2, and 10.8.2.1 shall apply.

The effects of wall movements on adjacent facilities shall be considered in the development of the wall design.

C11.9.1

Depending on soil conditions, anchors are usually required for support of both temporary and permanent nongravity cantilevered walls higher than about 10.0 to 15.0 ft.

The availability or ability to obtain underground easements and proximity of buried facilities to anchor locations should also be considered in assessing feasibility.

Anchored walls in cuts are typically constructed from the top of the wall down to the base of the wall. Anchored walls in fill must include provisions to protect against anchor damage resulting from backfill and subsoil settlement or backfill and compaction activities above the anchors.

The minimum distance between the front of the bond zone and the active zone behind the wall of 5.0 ft or $H/5$ is needed to ensure that no load from the bonded zone is transferred into the no load zone due to load transfer through the grout column in the no load zone.

C11.9.2

Lateral earth pressures on anchored walls are a function of the rigidity of the wall-anchor system, soil conditions, method and sequence of construction, and level of prestress imposed by the anchors. Apparent earth pressure diagrams that are commonly used can be found in Article 3.11.5.7 and Sabatini et al. (1999).

C11.9.3.1

Settlement of vertical wall elements can cause reduction of anchor loads, and should be considered in design.

The settlement profiles in Figure C11.9.3.1-1 were recommended by Clough and O'Rourke (1990) to estimate ground surface settlements adjacent to braced or anchored excavations caused during the excavation and bracing stages of construction. Significant settlements may also be caused by other construction activities, e.g., dewatering or deep foundation construction within the excavation, or by poor construction techniques, e.g., soldier pile, lagging, or anchor installation. The field measurements used to develop Figure C11.9.3.1-1 were screened by the authors to not include movements caused by other construction activities or poor construction techniques. Therefore, such movements should be estimated separately.

Where noted in the definition of the various curves in Figure C11.9.3.1-1, the basal heave ratio, R_{BH} , shall be taken as:

$$R_{BH} = \frac{5.1S_y}{\gamma H + q_s} \quad (C11.9.3.1-1)$$

where:

 S_u = undrained shear strength of cohesive soil (ksf)
$$\gamma = \text{unit weight of soil (kcf)}$$
$$H = \text{height of wall (ft)}$$
$$q_s = \text{surcharge pressure (ksf)}$$

See Sabatini et al. (1999) for additional information on the effect of anchored wall construction and design on wall movement.

Curve I = Sand

Curve II = Stiff to very hard clay

Curve III = Soft to medium clay, $R_{BH} = 2.0$

Curve IV = Soft to medium clay, $R_{BH} = 1.2$

Figure C11.9.3.1-1—Settlement Profiles behind Braced or Anchored Walls (adapted from Clough and O'Rourke, 1990)

11.9.4—Safety against Soil Failure

11.9.4.1—Bearing Resistance

The provisions of Articles 10.6.3, 10.7.3, and 10.8.3 shall apply.

Bearing resistance shall be determined assuming that all vertical components of loads are transferred to the embedded section of the vertical wall elements.

11.9.4.2—Anchor Pullout Capacity

Prestressed anchors shall be designed to resist pullout of the bonded length in soil or rock. The factored pullout resistance of a straight shaft anchor in soil or rock, Q_R , is determined as:

$$Q_R = \phi Q_n = \phi \pi D_{DH} \tau_u L_b \quad (11.9.4.2-1)$$

where:

- ϕ = resistance factor for anchor pullout (dim.)
- Q_n = nominal anchor pullout resistance (kips)
- D_{DH} = diameter of anchor drill hole (ft)
- τ_u = nominal anchor bond stress (ksf)
- L_b = anchor bond length (ft)

For preliminary design, the resistance of anchors may either be based on the results of anchor pullout load tests; estimated based on a review of geologic and boring data, soil and rock samples, laboratory testing, and previous experience; or estimated using published soil/rock-grout bond guidelines. For final design, the contract documents may require preproduction tests such as pullout tests or extended creep tests on sacrificial anchors be conducted to establish anchor lengths and capacities that are consistent with the contractor's chosen method of anchor installation. Either performance or proof tests shall be conducted on every production anchor to 1.0 or greater times the factored load to verify capacity.

C11.9.4.1

For drilled in place vertical wall elements, e.g., drilled-in soldier piles, in sands, if the β -method is used to calculate the skin friction capacity, the depth, z , should be referenced to the top of the wall. The vertical overburden stress, σ_v' , however, should be calculated with reference to the elevation of the midheight of the exposed wall, with β and σ_v' evaluated at the midpoint of each soil layer.

C11.9.4.2

Anchor pullout capacity is influenced by soil and rock conditions, method of anchor hole advancement, hole diameter, bonded length, grout type, and grouting pressure. Information on anchor pullout capacity may be found in Sabatini et al. (1999), PTI (1996), Cheney (1984), and Weatherby (1982). As a guide, the presumptive values provided in Tables C11.9.4.2-1, C11.9.4.2-2, and C11.9.4.2-3 may be used to estimate the nominal (ultimate) bond for small diameter anchors installed in cohesive soils, cohesionless soils, and rock, respectively. It should be recognized that the values provided in the tables may be conservative.

Table C11.9.4.2-1—Presumptive Ultimate Unit Bond Stress for Anchors in Cohesive Soils

Anchor/Soil Type (Grout Pressure)	Soil Stiffness or Unconfined Compressive Strength (tsf)	Presumptive Ultimate Unit Bond Stress, τ_u (ksf)
Gravity Grouted Anchors (<50 psi)		
Silt-Clay Mixtures	Stiff to Very Stiff 1.0–4.0	0.6 to 1.5
Pressure Grouted Anchors (50 psi– 400 psi)		
High Plasticity Clay	Stiff 1.0–2.5 V. Stiff 2.5–4.0	0.6 to 2 1.5 to 3.6
Medium Plasticity Clay	Stiff 1.0–2.5 V. Stiff 2.5–4.0	2.0 to 5.2 2.9 to 7.3
Medium Plasticity Sandy Silt	V. Stiff 2.5–4.0	5.8 to 7.9

Table C11.9.4.2-2—Presumptive Ultimate Unit Bond Stress for Anchors in Cohesionless Soils

Anchor/Soil Type (Grout Pressure)	Soil Compactness or <i>SPT</i> Resistance ^a	Presumptive Ultimate Unit Bond Stress, τ_u (ksf)
Gravity Grouted Anchors (<50 psi)		
Sand or Sand– Gravel Mixtures	Medium Dense to Dense 11–50	1.5 to 2.9
Pressure Grouted Anchors (50 psi– 400 psi)		
Fine to Medium Sand	Medium Dense to Dense 11–50	1.7 to 7.9
Medium to Coarse Sand w/ Gravel	Medium Dense 11–30	2.3 to 14
	Dense to Very Dense 30–50	5.2 to 20
Silty Sands	—	3.5 to 8.5
Sandy Gravel	Medium Dense to Dense 11–40	4.4 to 29
	Dense to Very Dense 40–50+	5.8 to 29
Glacial Till	Dense 31–50	6.3 to 11

^a Corrected for overburden pressure.

Table C11.9.4.2-3—Presumptive Ultimate Unit Bond Stress for Anchors in Rock

Rock Type	Presumptive Ultimate Unit Bond Stress, τ_u (ksf)
Granite or Basalt	36 to 65
Dolomitic Limestone	29 to 44
Soft Limestone	21 to 29
Slates & Hard Shales	17 to 29
Sandstones	17 to 36
Weathered Sandstones	15 to 17
Soft Shales	4.2 to 17

The presumptive ultimate anchor bond stress values presented in Tables C11.9.4.2-1 through C11.9.4.2-3 are intended for preliminary design or evaluation of the feasibility of straight shaft anchors installed in small diameter holes. Pressure-grouted anchors may achieve much higher capacities. The total capacity of a pressure-grouted anchor may exceed 500 kips in soil or 2,000 to 3,000 kips in rock, although such high capacity anchors are seldom used for highway applications. Post-grouting can also increase the load carrying capacity of straight shaft anchors by 20–50 percent or more per phase of post-grouting.

The resistance factors in Table 11.5.7-1, in combination with the load factor for horizontal active earth pressure (Table 3.4.1-2), are consistent with what would be required based on allowable stress design, for preliminary design of anchors for pullout (Sabatini et al., 1999). These resistance factors are also consistent with the results of statistical calibration of full-scale anchor pullout tests relative to the minimum values of presumptive ultimate unit bond stresses shown in Tables C11.9.4.2-1 through C11.9.4.2-3. Use of the resistance factors in Table 11.5.7-1 and the load factor for apparent earth pressure for anchor walls in Table 3.4.1-2, with values of presumptive ultimate unit bond stresses other than the minimum values in Tables C11.9.4.2-1 through C11.9.4.2-3 could result in unconservative designs unless the Engineer has previous experience with the particular soil or rock unit in which the bond zone will be established.

Presumptive bond stresses greater than the minimum values shown in Tables C11.9.4.2-1 through C11.9.4.2-3 should be used with caution, and be based on past successful local experience, such as a high percentage of passing proof tests in the specified or similar soil or rock unit at the design bond stress chosen, or anchor pullout test results in the specified or similar soil or rock unit. Furthermore, in some cases the specified range of presumptive bond stresses is representative of a range of soil conditions. Soil conditions at the upper end of the specified range, especially if coupled with previous experience with the particular soil unit, may be considered in the selection of anchor bond stresses above the minimum values shown. Selection of a presumptive bond stress for preliminary anchor sizing should consider the risk of failing proof tests if the selected bond stress was to be used for final design. The goal of preliminary anchor design is to reduce the risk of having a significant number of production anchors fail proof or performance tests as well as the risk of having to redesign the anchored wall to accommodate more anchors due to an inadequate easement behind the wall, should the anchor capacities predicted during preliminary design not be achievable. See Article 11.9.8.1 for guidance on anchor testing.

Significant increases in anchor capacity for anchor bond lengths greater than approximately 40.0 ft cannot be achieved unless specialized methods are used to transfer load from the top of the anchor bond zone towards the end of the anchor. This is especially critical for strain sensitive soils, in which residual soil strength is significantly lower than the peak soil strength.

Anchor inclination and spacing will be controlled by soil and rock conditions, the presence of geometric constraints and the required anchor capacity. For tremie-grouted anchors, a minimum angle of inclination of about 10 degrees and a minimum overburden cover of about 15.0 ft are typically required to assure grouting of the entire bonded length and to provide sufficient ground cover above the anchorage zone. For pressure-grouted

The anchor load shall be developed by suitable embedment outside of the critical failure surface in the retained soil mass.

Determination of the unbonded anchor length, inclination, and overburden cover shall consider:

- The location of the critical failure surface furthest from the wall,

- The minimum length required to ensure minimal loss of anchor prestress due to long-term ground movements,
- The depth to adequate anchoring strata, as indicated in Figure 11.9.1-1, and
- The method of anchor installation and grouting.

The minimum horizontal spacing of anchors should be the larger of three times the diameter of the bonded zone, or 5.0 ft. If smaller spacings are required to develop the required load, consideration may be given to differing anchor inclinations between alternating anchors.

11.9.4.3—Passive Resistance

The provisions of Articles 3.11.5.6, 11.6.3.5, 11.6.3.6, and 11.8.4.1 shall apply.

11.9.4.4—Overall Stability

The provisions of Articles 3.4.1 and 11.6.3.7 shall apply.

11.9.5—Safety against Structural Failure

11.9.5.1—Anchors

The horizontal component of anchor design force shall be computed using the provisions of Article 11.9.2 and any other horizontal pressure components acting on the wall in Article 3.11. The total anchor design force shall be determined based on the anchor inclination. The

anchors, the angle of inclination is generally not critical and is governed primarily by geometric constraints, and the minimum overburden cover is typically 6.0–15.0 ft. Steep inclinations may be required to avoid anchorage in unsuitable soil or rock. Special situations may require horizontal or near horizontal anchors, in which case proof of sufficient overburden and full grouting should be required.

The minimum horizontal spacing specified for anchors is intended to reduce stress overlap between adjacent anchors.

Anchors used for walls constructed in fill situations, i.e., bottom-up construction, should be enclosed in protective casing to prevent damage during backfill placement, compaction, and settlement.

Selection of anchor type depends on anticipated service life, soil and rock conditions, ground water level, subsurface environmental conditions, and method of construction.

C11.9.4.3

It is recommended in Sabatini et al. (1999) that methods such as the Broms Method or the Wang and Reese Method be used to evaluate passive resistance and the wall vertical element embedment depth needed. However, these methods have not been calibrated for this application for LRFD.

If the effective width of the discrete vertical elements of the wall is increased to greater than the physical width of the vertical elements, the background regarding this issue as described in Article C3.11.5.6 applies.

C11.9.4.4

Detailed guidance for evaluating the overall stability of anchored wall systems, including how to incorporate anchor forces in limit equilibrium slope stability analyses, is provided by Sabatini et al. (1999).

The effect of discrete vertical elements penetrating deep failure planes and acting as in-situ soil improvement may be negligible if the percentage of reinforcement provided by the vertical elements along the failure surface is small. However, it is possible to consider the effect of the discrete vertical elements by modeling the elements as a cohesion along the failure surface, or by evaluating the passive capacity of the elements.

C11.9.5.1

Anchor tendons typically consist of steel bars, wires, or strands. The selection of anchor type is generally the responsibility of the contractor.

A number of suitable methods for the determination of anchor loads are in common use. Sabatini et al. (1999)

horizontal anchor spacing and anchor capacity shall be selected to provide the required total anchor design force.

provide two methods which can be used: the Tributary Area Method, and the Hinge Method. These methods are illustrated in Figures C11.9.5.1-1 and C11.9.5.1-2. These figures assume that the soil below the base of the excavation has sufficient strength to resist the reaction force, R . If the soil providing passive resistance below the base of the excavation is weak and is inadequate to carry the reaction force, R , the lowest anchor should be designed to carry both the anchor load as shown in the figures as well as the reaction force. See Article 11.8.4.1 for evaluation of passive resistance. Alternatively, soil-structure interaction analyses, e.g., beam on elastic foundation, can be used to design continuous beams with small toe reactions, as it may be overly conservative to assume that all of the load is carried by the lowest anchor.

In no case should the maximum test load be less than the factored load for the anchor.

Figure C11.9.5.1-1—Calculation of Anchor Loads for One-Level Wall after Sabatini et al. (1999)

Figure C11.9.5.1-2—Calculation of Anchor Loads for Multilevel Wall after Sabatini et al. (1999)

11.9.5.2—Vertical Wall Elements

Vertical wall elements shall be designed to resist all horizontal earth pressure, surcharge, water pressure, anchor, and seismic loadings, as well as the vertical component of the anchor loads and any other vertical loads. Horizontal supports may be assumed at each anchor location and at the bottom of the excavation if the vertical element is sufficiently embedded below the bottom of the excavation.

C11.9.5.2

Discrete vertical wall elements are continuous throughout their length and include driven piles, caissons, drilled shafts, and auger-cast piles, i.e., piles and built-up sections installed in preaugured holes and backfilled with structural concrete in the passive zone and lean concrete in the exposed section of the wall.

Continuous vertical wall elements are continuous throughout both their length and width, although vertical joints may prevent shear and/or moment transfer between adjacent sections. Continuous vertical wall elements include sheet piles, precast or cast-in-place concrete diaphragm wall panels, tangent-piles, and tangent caissons.

For structural analysis methods, see Section 4.

For walls supported in or through soft clays with $S_u < 0.15\gamma'H$, continuous vertical elements extending well below the exposed base of the wall may be required to prevent heave in front of the wall. Otherwise, the vertical elements are embedded approximately 3.0 ft or as required for stability or end bearing.

11.9.5.3—Facing

The provisions of Article 11.8.5.2 shall apply.

11.9.6—Seismic Design

The provisions of Article 11.8.6 shall apply except as modified in this Article.

The seismic analysis of the anchored retaining wall shall demonstrate that the anchored wall can maintain overall stability and withstand the seismic earth pressures induced by the design earthquake without exceeding the capacity of the anchors or the structural wall section supporting the soil. Limit equilibrium methods or numerical displacement analyses shall be used to confirm acceptable wall performance.

Anchors shall be located behind the limit equilibrium failure surface for seismic loading. The location of the failure surface for seismic loading shall be established using methods that account for the seismic coefficient and the soil properties (i.e., soil friction angles and soil cohesion values) within the anchored zone.

C11.9.6

See Article C11.8.6.

The seismic design of an anchored wall involves many of the same considerations as the nongravity cantilever wall. However, the addition of one or more anchors to the wall introduces some important differences in the seismic design check as identified in this Article.

The earth pressures above the excavation level result from the inertial response of the soil mass behind the wall. In contrast to a nongravity cantilever wall, the soil mass includes anchors that have been tensioned to minimize wall deflections under static earth pressures. During seismic loading, the bars or strands making up the unbonded length of the anchor are able to stretch under the imposed incremental seismic loads. In most cases, the amount of elastic elongation in the strand or bar under the incremental seismic load is sufficient to develop seismic active earth pressures but may not be sufficient to allow the horizontal seismic acceleration coefficient, k_{h0} , and associated earth pressure to be reduced to account for permanent horizontal wall displacement. The ability of the wall to deform laterally should be specifically investigated before reducing the value of k_{h0} to account for horizontal wall displacement.

The passive pressure for the embedded portion of the soldier pile or sheet pile wall also plays a part in the stability assessment, as it helps provide stability for the portion of the wall below the lowest anchor. This passive pressure is subject to seismically induced inertial forces that will reduce the passive resistance relative to the static capacity of the pile or wall section. Most often, the embedded portion of the pile involves discrete structural members spaced at 8.0 to 10.0 ft; however, the embedded portion could also involve a continuous wall in the case of a sheet pile or secant pile wall.

Anchors should be located behind the failure surface associated with the calculation of P_{AE} . The location of this failure surface can be determined using either the wedge equilibrium or the GLE (slope stability) method. Note that this failure surface will likely be flatter than the requirements for anchor location under static loading. When using the wedge equilibrium or the GLE method, P_{AE} and its associated critical surface should be determined without the anchor forces.

Once the location of the anchor bond zone is defined, an external stability check should be conducted with the anchor forces included, using the anchor test load to define ultimate anchor capacities. This check is performed to confirm that the C/D ratio is greater than 1.0. Under this loading condition, the critical surface will flatten and could pass through or behind some anchors. However, as long as the C/D ratio is greater than 1.0, the design is satisfactory.

If the C/D ratio is less than 1.0, either the unbonded length of the anchor must be increased or the length of the grouted zone must be lengthened. The design check would then be repeated.

The global stability check is performed to confirm that a slope stability failure does not occur below the anchored wall; external stability is checked to confirm the anchors will have sufficient reserve capacity to meet seismic load demands; and internal stability is checked to confirm that moments and shear forces within the structural members, including the anchor strand or bar tensile loads and the head connection, are within acceptable levels for the seismic load.

11.9.7—Corrosion Protection

Prestressed anchors and anchor heads shall be protected against corrosion consistent with the ground and groundwater conditions at the site. The level and extent of corrosion protection shall be a function of the ground environment and the potential consequences of an anchor failure. Corrosion protection shall be applied in accordance with the provisions of *AASHTO LRFD Bridge Construction Specifications*, Section 6.

11.9.8—Construction and Installation

11.9.8.1—Anchor Stressing and Testing

All production anchors shall be subjected to load testing and stressing in accordance with the provisions of Article 6.5.5 of the *AASHTO LRFD Bridge Construction Specifications*. Preproduction load tests may be specified when unusual conditions are encountered to verify the safety with respect to the design load to establish the ultimate anchor load (pullout test), or to identify the load at which excessive creep occurs.

At the end of the testing of each production anchor, the anchor should be locked off to take up slack in the anchored wall system to reduce post-construction wall deformation. The lock-off load should be determined and applied as described in Article 6.5.5.6 of the *AASHTO LRFD Bridge Construction Specifications*.

C11.9.7

Corrosion protection for piles, wales, and miscellaneous hardware and material should be consistent with the level of protection for the anchors and the design life of the structure.

C11.9.8.1

Common anchor load tests include pullout tests performed on sacrificial preproduction anchors and creep, performance, and proof tests performed on the production anchors. None of the production anchor tests determine the actual ultimate anchor load capacity. The production anchor test results only provide an indication of serviceability under a specified load. Performance tests consist of incremental loading and unloading of anchors to verify sufficient capacity to resist the test load, verify the free length, and evaluate the permanent set of the anchor. Proof tests, usually performed on each production anchor, consist of a single loading and unloading cycle to verify sufficient capacity to resist the test load and to prestress the anchor. Creep tests, recommended for cohesive soils with a plasticity index greater than 20 percent or a liquid limit greater than 50 percent, and highly weathered, soft rocks, consist of incremental, maintained loading of anchors to assess the potential for loss of anchor bond capacity due to ground creep.

Pullout tests should be considered in the following circumstances:

- If the preliminary anchor design using unit bond stresses provided in the previous tables indicate that anchored walls are marginally infeasible, requiring that a more accurate estimate of anchor capacity be obtained during wall design. This may occur due to lack of adequate room laterally to accommodate the estimated anchor length within the available right-of-way or easement.
- If the anticipated anchor installation method or soil/rock conditions are significantly different than those assumed to develop the presumptive values in Tables C11.9.4.2-1 through

C11.4.9.2-3 and inadequate site-specific experience is available to make a reasonably accurate estimate of the soil/rock-grout anchor bond stresses.

The FHWA recommends load testing anchors to 125 percent to 150 percent of the unfactored design load, Cheney (1984). Maximum load levels between 125 percent and 200 percent have been used to evaluate the potential for tendon overstress in service, to accommodate unusual or variable ground conditions or to assess the effect of ground creep on anchor capacity. Test load levels greater than 150 percent of the unfactored design load are normally applied only to anchors in soft cohesive soil or unstable soil masses where loss of anchor prestress due to creep warrants evaluation. The area of prestressing steel in the test anchor tendon may require being increased to perform these tests.

Note that the test details provided in Article 6.5.5 of the *AASHTO LRFD Bridge Construction Specifications*, at least with regard to the magnitude of the incremental test loads, were developed for allowable stress design. These incremental test loads should be divided by the load factor for apparent earth pressure for anchored walls provided in Table 3.4.1-2 when testing to factored anchor loads.

Typically, the anchor lock-off load is equal to 80 to 100 percent of the nominal (unfactored) anchor load to ensure that the slack in the anchored wall system is adequately taken up so that post-construction wall deformation is minimized. However, a minimum lock-off load of 50 percent is necessary to properly engage strand anchor head wedges.

11.9.9—Drainage

The provisions of Article 11.8.8 shall apply.

C11.9.9

Thin drains at the back of the wall face may not completely relieve hydrostatic pressure and may increase seepage forces on the back of the wall face due to rainwater infiltration (Terzaghi and Peck, 1967) (Cedergren, 1989). The effectiveness of drainage control measures should be evaluated by seepage analyses.

11.10—MECHANICALLY STABILIZED EARTH WALLS

11.10.1—General

MSE walls may be considered where conventional gravity, cantilever, or counterforted concrete retaining walls and prefabricated modular retaining walls are considered, and particularly where substantial total and differential settlements are anticipated.

When two intersecting walls form an enclosed angle of 70 degrees or less, the affected portion of the wall shall be designed as an internally tied bin structure with at-rest earth pressure coefficients.

MSE walls shall not be used under the following conditions:

C11.10.1

MSE systems, whose elements may be proprietary, employ either metallic (strip or grid type) or geosynthetic (geotextile, strip, or geogrid) tensile reinforcements in the soil mass, and a facing element which is vertical or near vertical. MSE walls behave as a gravity wall, deriving their lateral resistance through the dead weight of the reinforced soil mass behind the facing. For relatively thick facings, the dead weight of the facing may also provide a significant contribution to the capacity of the wall system. Typical MSE walls are shown in Figure C11.10.1-1.

- Where utilities other than highway drainage are to be constructed within the reinforced zone unless access is provided to utilities without disrupting reinforcements and breakage or rupture of utility lines will not have a detrimental effect on the stability of the structure.
- Where floodplain erosion or scour may undermine the reinforced fill zone or facing, or any supporting footing.
- With reinforcements exposed to surface or ground water contaminated by acid mine drainage, other industrial pollutants, or other environmental conditions defined as aggressive in Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*, unless environment-specific, long-term corrosion, or degradation studies are conducted.

All available data indicate that corrosion in MSE walls is not accelerated by stray currents from electric rail lines due to the discontinuity of the earth reinforcements in a direction parallel to the source of the stray current. Where metallic reinforcements are used in areas of anticipated stray currents within 200 ft of the structure, and the metallic reinforcements are continuously connected in a direction parallel to the source of stray currents, a corrosion expert should evaluate the potential need for corrosion control requirements. More detailed information on stray current corrosion issues is provided by Sankey and Anderson (1999).

Where future access to utilities may be gained without disrupting reinforcements and where leakage from utilities would not create detrimental hydraulic conditions or degrade reinforcements, utilities in the reinforced zone may be acceptable.

The potential for catastrophic failure due to scour is high for MSE walls if the reinforced fill is lost during a scour occurrence. Consideration should be given to lowering the base of the wall or to adopt scour countermeasures such as sheetpile walls and/or riprap of sufficient size, placed to a sufficient depth to preclude scour. Alternative wall types should also be considered.

Figure C11.10.1-1—Typical Mechanically Stabilized Earth Walls

MSE walls shall be designed for external stability of the wall system as well as internal stability of the reinforced soil mass behind the facing. Overall and compound stability failure shall be considered. Structural design of the wall facing shall also be considered.

The specifications provided herein for MSE walls do not apply to geometrically complex MSE wall systems such as tiered walls (walls stacked on top of one another), back-to-back walls, or walls which have trapezoidal sections. Design guidelines for these cases are provided in FHWA-NHI-10-024 (Berg et al., 2009). Compound stability should also be evaluated for these complex MSE wall systems (see Article 11.10.5.6).

For simple structures with rectangular geometry, relatively uniform reinforcement spacing, and a near vertical face, compound failures passing both through the unreinforced and reinforced zones will not generally be critical. However, if complex conditions exist such as changes in reinforced soil types or reinforcement lengths, high surcharge loads, sloping faced structures, a slope at the toe of the wall, or stacked structures, compound failures must be considered.

Internal design of MSE wall systems requires knowledge of short- and long-term properties of the materials used as soil reinforcements as well as the soil mechanics which govern MSE wall behavior.

11.10.2—Structure Dimensions

An illustration of the MSE wall element dimensions required for design is provided in Figure 11.10.2-1.

The size and embedment depth of the reinforced soil mass shall be determined based on:

- Requirements for stability and geotechnical strength, as specified in Article 11.10.5 consistent with requirements for gravity walls,
- Requirements for structural resistance within the reinforced soil mass itself, as specified in Article 11.10.6, for the panel units, and for the development of reinforcement beyond assumed failure zones, and
- Traditional requirements for reinforcement length not less than 70 percent of the wall height, except as noted in Article 11.10.2.1.

For external and internal stability calculations, the weight and dimensions of the facing elements are typically ignored. However, it is acceptable to include the facing dimensions and weight in sliding and bearing capacity calculations. For internal stability calculations, the wall dimensions are considered to begin at the back of the facing elements.

Figure 11.10.2-1—MSE Wall Element Dimensions Needed for Design

11.10.2.1—Minimum Length of Soil Reinforcement

For sheet-, strip-, and grid-type reinforcement, the minimum soil reinforcement length shall be 70 percent of the wall height as measured from the leveling pad. Reinforcement length shall be increased as required for surcharges and other external loads, or for soft foundation soils.

The reinforcement length shall be uniform throughout the entire height of the wall, unless

C11.10.2.1

In general, a minimum reinforcement length of 8.0 ft, regardless of wall height, has been recommended based on historical practice, primarily due to size limitations of conventional spreading and compaction equipment. Shorter minimum reinforcement lengths, on the order of 6.0 ft, but no less than 70 percent of the wall height, can be considered if smaller compaction equipment is used, facing panel alignment can be maintained, and minimum requirements for wall external stability are met.

Significant shortening of the reinforcement elements below the minimum recommended ratio of $0.7H$ may only be considered when accurate, site specific determinations of the strength of the unreinforced fill and the foundation soil have been made. Christopher et al. (1990) present results which strongly suggest that shorter reinforcing length to height ratios, i.e., $0.5H$ to $0.6H$, substantially increase horizontal deformations.

A nonuniform reinforcement length may be considered under the following circumstances:

substantiating evidence is presented to indicate that variation in length is satisfactory.

- Lengthening of the uppermost reinforcement layers to beyond $0.7H$ to meet pullout requirements, or to address seismic or impact loads.
- Lengthening of the lowermost reinforcement layers beyond $0.7H$ to meet overall (global) stability requirements based on the results of a detailed global stability analysis.
- Shortening of the bottom reinforcement layers to less than $0.7H$ to minimize excavation requirements, provided the wall is bearing on rock or very competent foundation soil (see below).

For walls on rock or very competent foundation soil, e.g., $SPT > 50$, the bottom reinforcements may be shortened to a minimum of $0.4H$ with the upper reinforcements lengthened to compensate for external stability issues in lieu of removing rock or competent soil for construction. Design guidelines for this case are provided in FHWA-NHI-10-024 (Berg et al., 2009).

For conditions of marginal stability, consideration must be given to ground improvement techniques to improve foundation stability, or to lengthening of reinforcement.

11.10.2.2—Minimum Front Face Embedment

The minimum embedment depth of the bottom of the reinforced soil mass (top of the leveling pad) shall be based on bearing resistance, settlement, and stability requirements determined in accordance with Section 10.

Unless constructed on rock foundations, the embedment at the front face of the wall in ft shall not be less than:

- a depth based on the prevailing depth of frost penetration, if the soil below the wall is frost-susceptible, and the external stability requirement, and
- 2.0 ft on sloping ground ($4.0H:1V$ or steeper) or where there is potential for removal of the soil in front of the wall toe due to erosion or future excavation, or 1.0 ft on level ground where there is no potential for erosion or future excavation of the soil in front of the wall toe.

For walls constructed along rivers and streams, Article 11.6.3.4 applies, except that the embedment depth shall be established at a minimum of 2.0 ft below total scour depth for the scour check flood.

As an alternative to locating the wall base below the depth of frost penetration where frost-susceptible soils are present, the soil within the depth and lateral extent of frost penetration below the wall can be removed and replaced with nonfrost-susceptible clean granular soil.

A minimum horizontal bench width of 4.0 ft shall be provided in front of walls founded on slopes. The bench

C11.10.2.2

The minimum embedment guidelines provided in Table C11.10.2.2-1 may be used to preclude local bearing resistance failure under the leveling pad or footing due to higher vertical stresses transmitted by the facing.

Table C11.10.2.2-1—Guide for Minimum Front Face Embedment Depth

Slope in Front of Structures		Minimum Embedment Depth
Horizontal	for walls	$H/20.0$
	for abutments	$H/10.0$
$3.0H:1.0V$	walls	$H/10.0$
$2.0H:1.0V$	walls	$H/7.0$
$1.5H:1.0V$	walls	$H/5.0$

For structures constructed on slopes, minimum horizontal benches are intended to provide resistance to local bearing resistance failure consistent with resistance to general bearing resistance failure and to provide access for maintenance inspections.

may be formed or the slope continued above that level as shown in Figure 11.10.2-1.

The lowest backfill reinforcement layer shall not be located above the long-term ground surface in front of the wall.

11.10.2.3—Facing

Facing elements shall be designed to resist the horizontal force in the soil reinforcements at the reinforcement to facing connection, as specified in Articles 11.10.6.2.2 and 11.10.7.3.

In addition to these horizontal forces, the facing elements shall also be designed to resist potential compaction stresses occurring near the wall face during erection of the wall.

The tension in the reinforcement may be assumed to be resisted by a uniformly distributed earth pressure on the back of the facing.

The facing shall be stabilized such that it does not deflect laterally or bulge beyond the established tolerances.

11.10.2.3.1—Stiff or Rigid Concrete, Steel, and Timber Facings

Facing elements shall be structurally designed in accordance with Sections 5, 6, and 8 for concrete, steel, and timber facings, respectively.

The minimum thickness for concrete panels at, and in the zone of stress influence of, embedded connections shall be 5.5 in. and 3.5 in. elsewhere. The minimum concrete cover shall be 1.5 in. Reinforcement shall be provided to resist the average loading conditions for each panel. Temperature and shrinkage steel shall be provided as specified in Article 5.10.6.

The structural integrity of concrete face panels shall be evaluated with respect to the shear and bending moment between reinforcements attached to the facing panel in accordance with Section 5.

For segmental concrete facing blocks, facing stability calculations shall include an evaluation of the maximum vertical spacing between reinforcement layers, the maximum allowable facing height above the uppermost reinforcement layer, inter-unit shear capacity, and resistance of the facing to bulging. The maximum spacing between reinforcement layers shall be limited to twice the width, W_u , illustrated in Figure 11.10.6.4.4b-1, of the segmental concrete facing block unit or 2.7 ft, whichever is less, subject to the limitations provided in Article 11.10.6.2.1. The maximum facing height up to the wall surface grade above the uppermost reinforcement layer shall be limited to $1.5W_u$ illustrated in Figure 11.10.6.4.4b-1 or 24.0 in., whichever is less, provided that the facing above the uppermost reinforcement layer is demonstrated to be stable against a toppling failure through detailed calculations. The maximum depth of facing below the lowest

C11.10.2.3

See Article C3.11.2 for guidance. Additional information on compaction stresses can be found in Duncan and Seed (1986) and Duncan et al. (1991). Alternatively, compaction stresses can be addressed through the use of facing systems which have a proven history of being able to resist the compaction activities anticipated behind the wall and which have performed well in the long-term.

C11.10.2.3.1

The specified minimum panel thicknesses and concrete cover recognize that MSE walls are often employed where panels may be exposed to salt spray and/or other corrosive environments. The minimum thicknesses also reflect the tolerances on panel thickness, and placement of reinforcement and connectors that can reasonably be conformed to in precast construction.

Based on research by Allen and Bathurst (2015), facings consisting of segmental concrete facing blocks behave as a stiff facing, due to the ability of the facing blocks to transmit moment in a vertical direction throughout the facing column, and appear to have even greater stiffness than incremental precast concrete panels.

Experience has shown that for walls with segmental concrete block facings, the gap between soil reinforcement sections or strips at a horizontal level should be limited to a maximum of one block width to limit bulging of the facing between reinforcement levels or build-up of stresses that could result in performance problems. The ability of the facing to carry moment horizontally to bridge across the gaps in the reinforcement horizontally should be evaluated if horizontally discontinuous reinforcement is used, i.e., a reinforcement coverage ratio $R_c < 1$.

reinforcement layer shall be limited to the width, W_u , of the proposed segmental concrete facing block unit.

11.10.2.3.2—Flexible Wall Facings

If welded wire, expanded metal, or similar facing is used, it shall be designed in a manner which prevents the occurrence of excessive bulging as backfill behind the facing compresses due to compaction stresses or self-weight of the backfill. This may be accomplished by limiting the size of individual facing elements vertically and the vertical and horizontal spacing of the soil reinforcement layers, and by requiring the facing to have an adequate amount of vertical slip and overlap between adjacent elements.

The top of the flexible facing at the top of the wall shall be attached to a soil reinforcement layer to provide stability to the top facing.

Geosynthetic facing elements shall not, in general, be left exposed to sunlight (specifically ultraviolet radiation) for permanent walls. If geosynthetic facing elements must be left exposed permanently to sunlight, the geosynthetic shall be stabilized to be resistant to ultraviolet radiation. Product-specific test data shall be provided which can be extrapolated to the intended design life and which proves that the product will be capable of performing as intended in an exposed environment.

11.10.2.3.3—Corrosion Issues for MSE Facing

Steel-to-steel contact between the soil reinforcement connections and the concrete facing steel reinforcement shall be prevented so that contact between dissimilar metals, e.g., bare facing reinforcement steel and galvanized soil reinforcement steel, does not occur.

A corrosion protection system shall be provided where salt spray is anticipated.

11.10.3—Loading

The provisions of Article 11.6.1.2 shall apply, except that shrinkage and temperature effects need not be considered to come in contact with steel wall elements.

11.10.4—Movement at the Service Limit State

11.10.4.1—Settlement

The provisions of Article 11.6.2 shall apply as applicable.

The allowable settlement of MSE walls shall be established based on the longitudinal deformability of the facing and the ultimate purpose of the structure.

C11.10.2.3.2

Experience has shown that for welded wire, expanded metal, or similar facings, vertical reinforcement spacing should be limited to a maximum of 2.0 ft and the gap between soil reinforcement at a horizontal level limited to a maximum of 3.0 ft to limit bulging of the panels between reinforcement levels. The section modulus of the facing material should be evaluated and calculations provided to support reinforcement spacings, which will meet the bulging requirements stated in Article C11.10.4.2.

C11.10.2.3.3

Steel-to-steel contact in this case can be prevented through the placement of a nonconductive material between the soil reinforcement face connection and the facing concrete reinforcing steel. Examples of measures which can be used to mitigate corrosion include, but are not limited to, coatings, sealants, or increased panel thickness.

C11.10.4.1

For systems with rigid concrete facing panels and with a maximum joint width of 0.75 in., the maximum tolerable slope resulting from calculated differential settlement may be taken as given in Table C11.10.4.1-1.

Where foundation conditions indicate large differential settlements over short horizontal distances, vertical full-height slip joints shall be provided.

Differential settlement from the front to the back of the wall shall also be evaluated, especially regarding the effect on facing deformation, alignment, and connection stresses.

11.10.4.2—Lateral Displacement

Lateral wall displacements shall be estimated as a function of overall structure stiffness, compaction intensity, soil type, reinforcement length, slack in reinforcement-to-facing connections, and deformability of the facing system or based on monitored wall performance.

Table C11.10.4.1-1—Guide for Limiting Distortion for Precast Concrete Facings of MSE Walls

Joint Width (in.)	Limiting Differential Settlement	
	Area $\leq 30 \text{ ft}^2$	$30 \text{ ft}^2 \leq \text{Area} \leq 75 \text{ ft}^2$
0.75	1/100	1/200
0.50	1/200	1/300
0.25	1/300	1/600

For MSE walls with full height precast concrete facing panels, total settlement should be limited to 2.0 in., and the limiting differential settlement should be 1/500. For walls with segmental concrete block facings, the limiting differential settlement should be 1/200. For walls with welded wire facings or walls in which cast-in-place concrete or shotcrete facing is placed after wall settlement is essentially complete, the limiting differential settlement should be 1/50. These limiting differential settlement criteria consider only structural needs of the facing. More stringent differential settlement criteria may be needed to meet aesthetic requirements.

C11.10.4.2

A first order estimate of lateral wall displacements occurring during wall construction for simple MSE walls on firm foundations can be obtained from Figure C11.10.4.2-1. If significant vertical settlement is anticipated or heavy surcharges are present, lateral displacements could be considerably greater. Figure C11.10.4.2-1 is appropriate as a guide to establish an appropriate wall face batter to obtain a near vertical wall or to determine minimum clearances between the wall face and adjacent objects or structures.

Based on 20 ft high walls, relative displacement increases approximately 25 percent for every 400 psf of surcharge. Experience indicates that for higher walls, the surcharge effect may be greater.

Note: This figure is only a guide. Actual displacement will depend, in addition to the parameters address in the figure, on soil characteristics, compaction effort, and contractor workmanship.

Figure C11.10.4.2-1—Empirical Curve for Estimating Anticipated Lateral Displacement during Construction for MSE Walls

For additional explanation on how to use this figure, see Berg et al. (2009).

For welded wire or similarly faced walls such as gabion faced walls, the maximum tolerable facing bulge between connections, both horizontally and vertically, with soil reinforcement is approximately 2.0 in. For geosynthetic facings, the maximum facing bulge between reinforcement layers should be approximately 2.75 in. for 1.0 ft vertical reinforcement spacing to 5.0 in. for 2.0 ft vertical reinforcement spacing.

In cases where significant deformation of the wall face during or after wall construction is unavoidable, adjustment to the wall face batter should be considered. Additional facing offset at the wall toe may be needed to prevent buildup of lateral stress on existing structures in front of the wall, including more rigid second stage facing placed during or after wall construction.

11.10.4.3—Soil Failure (Internal Stability)

For reinforcement load prediction methods developed empirically from measurements, the wall shall be designed to prevent failure of the soil within the reinforced soil mass, thus preserving the conditions under which the empirical data were obtained. Reinforced fill soil failure is defined to occur when the strain in the reinforcement exceeds a value sufficient to allow the soil to reach or exceed its peak shear strength, and a contiguous shear failure zone within the reinforced wall backfill develops.

For the Stiffness Method as described in Article 11.10.6.2.1e, to prevent soil failure, the reinforcement strain ϵ_{rein} in individual layers shall be as follows for extensible reinforcement:

$$\epsilon_{rein} = \frac{\gamma_{p-EVsf} T_{max}}{\phi_{sf} J_i} \leq \epsilon_{mxmx} \quad (11.10.4.3-1)$$

where:

- ϵ_{rein} = the reinforcement strain in any individual reinforcement layer corresponding to T_{max} (percent)
- γ_{p-EVsf} = load factor for prediction of T_{max} for the soil failure limit state (dim.)
- T_{max} = the maximum load in the reinforcement at each reinforcement level, as specified in Article 11.10.6.2.1e (kips/ft)
- ϕ_{sf} = resistance factor that accounts for uncertainty in the measurement of the reinforcement stiffness at the specified strain (dim.)
- J_i = reinforcement layer secant stiffness (kips/ft)
- ϵ_{mxmx} = maximum acceptable strain in the wall cross-section corresponding to T_{max} in any reinforcement layer (percent)

C11.10.4.3

Soil failure for internal stability of MSE walls is considered a service limit state for design because it is based on a deformation criterion. Furthermore, if this criterion is substantially exceeded, the structure will not collapse but will more likely develop progressive increases in facing deformation.

Research indicates that if the average peak reinforcement strain in the wall exceeds 2.5 to 3 percent, for typical granular backfill materials, soil failure can occur (Allen et al., 2003) (Allen and Bathurst, 2013; 2015; 2018). Since ϵ_{mxmx} is a deterministic limit, ϵ_{mxmx} is set 0.5 percent lower than this to provide an additional margin of safety to ensure that soil failure does not occur.

For selection of the target strain criterion ϵ_{mxmx} , of 2.0 or 2.5 percent, a stiff faced wall is defined as having a facing stiffness factor, Φ_{fs} , as determined in Article 11.10.6.2.1e, of less than approximately 1.0. A flexible faced wall is therefore defined as having a facing stiffness factor of approximately 1.0. Typically, stiff faced walls include walls with a concrete panel or block facing, and flexible faced walls include geosynthetic wrap, welded wire, or gabion faced walls as well as two stage walls in which the concrete facing is installed at the end of the wall construction. If the wall is constructed using what is traditionally considered a stiff facing, but the facing stiffness factor is calculated to be approximately 1.0 or is conservatively assumed to be equal to 1.0 (see Article C11.10.6.2.1e), the higher strain criterion, ϵ_{mxmx} , of 2.5 percent may be considered for the wall design for this limit state.

Of the three empirically-based design methods used to estimate reinforcement loads, only the Stiffness Method directly addresses soil failure. Historically, the other two empirically based methods identified in these Specifications (i.e., the Simplified and Coherent Gravity methods) have been safely used without directly assessing soil failure as a limit state. For geosynthetic walls, these two methods have been demonstrated to be

J_i , the reinforcement layer secant stiffness, should be determined at a strain of 2 percent for geogrids and geotextiles. J_i should be determined at 1,000 hrs or the estimated time to complete the wall, as specified in AASHTO R 69. ϕ_{sf} is as specified in Table 11.5.7-1.

The maximum acceptable strain in each reinforcement layer ε_{max} corresponding to T_{max} should be set at 2 percent strain for stiff faced walls and 2.5 percent strain for flexible faced walls. These criteria have the objective of preventing the development of a contiguous shear surface through the reinforced soil zone.

For steel reinforced walls, soil failure does not need to be evaluated, provided the final design steel stress is less than F_y .

overly conservative relative to measured values (Allen et al., 2002; 2003) (Allen and Bathurst, 2002a; 2002b; 2013; 2014a, 2014b) (Bathurst et al., 2008) (Rowe and Ho, 1993), and for steel reinforced walls, the requirement to be below F_y ensures that the strains in the system remain very low. Therefore, soil failure is not required to be assessed for the Simplified and Coherent Gravity methods.

Regarding the Limit Equilibrium Method, failure of both the reinforcement and the soil are addressed in the strength limit state (Leshchinsky et al., 2016).

For design using the Stiffness Method, this limit state tends to control the strength of the reinforcement needed, especially in the upper half of the wall. The stiffness used to meet this limit state should be determined as a first step. Subsequently, this minimum required stiffness is used to determine T_{max} for the reinforcement rupture, connection rupture, and pullout limit states. The ultimate reinforcement tensile strength, T_{ult} , required to meet the reinforcement rupture and connection rupture limits may be less than the ultimate tensile strength of geosynthetic products with the minimum stiffness needed to prevent soil failure. In this case, prevention of soil failure is controlling the strength of the geosynthetic reinforcement needed. Geosynthetic reinforcement test report data which provide the relationship between reinforcement stiffness and T_{ult} are available from the AASHTO Product Evaluation & Audit Solutions program.

For additional details and examples of how to assess the prevention of soil failure when using the Stiffness Method, see Allen and Bathurst (2018).

For geostrip walls, working strains tend to be lower than for other geosynthetics based on strain measurements observed in full-scale geostrip walls (Miyata et al., 2018), and J_i determined at a strain level of 1 percent may be more appropriate.

11.10.5—Safety against Soil Failure (External Stability)

11.10.5.1—General

MSE structures shall be proportioned to satisfy eccentricity and sliding criteria normally associated with gravity structures.

Safety against soil failure shall be evaluated by assuming the reinforced soil mass to be a rigid body. The coefficient of active earth pressure, k_a , used to compute the earth pressure of the retained soil behind the reinforced soil mass shall be determined using the friction angle of the retained soil. In the absence of specific data, a maximum friction angle of 30 degrees may be used for granular soils. Tests should be performed to determine the friction angle of cohesive soils considering both drained and undrained conditions.

C11.10.5.1

Eccentricity requirements seldom govern design. Sliding and overall stability usually govern design of structures greater than 30.0 ft in height, structures constructed on weak foundation soils, or structures loaded with sloping surcharges.

11.10.5.2—Loading

Lateral earth pressure distributions for external stability design of MSE walls shall be taken as specified in Article 3.11.5.8. Application of loads for external stability shall be taken as specified in Articles 11.10.5 and 11.10.6, respectively. Application of surcharge and other external loads shall be taken as specified in Articles 11.10.10 and 11.10.11. Application of load factors for these loads shall be taken as specified in Article 11.5.6.

For external stability calculations only, the active earth pressure coefficients for retained backfill, i.e., fill behind the reinforced soil mass, shall be taken as specified in Article 3.11.5.3 with δ equal to no greater than $0.67 \phi'_f$ of the reinforced zone or retained zone, whichever is less.

Dead load surcharges, if present, shall be taken into account in accordance with Article 11.10.10.

For investigation of sliding stability and eccentricity, the continuous traffic surcharge loads shall be considered to act beyond the end of the reinforced zone as shown in Figure 11.10.5.2-1. Application of load factors for these loads shall be taken as specified in Article 11.5.6.

Figure 11.10.5.2-1—External Stability for Wall with Horizontal Backslope and Traffic Surcharge

11.10.5.3—Sliding

The provisions of Article 10.6.3.4 shall apply.

Sliding stability of MSE walls shall be evaluated at the base of the bottom of the wall facing and, as a minimum, at the interface between the soil and reinforcement for the lowest reinforcement layer. The coefficient of sliding friction at the base of the reinforced soil mass shall be determined using the friction angle of the foundation soil, ϕ_f , or reinforced fill soil, ϕ_r .

For discontinuous reinforcements, e.g., strips, the angle of sliding friction shall be taken as the lesser of ϕ_r of the reinforced fill and ϕ_f of the foundation soil. For continuous reinforcements, e.g., grids and sheets, the angle

C11.10.5.2

Figures 3.11.5.8.1-1, 3.11.5.8.1-2, and C3.11.5.8.1-1 illustrate lateral earth pressure distributions for external stability of MSE walls with horizontal backslope, inclined backslope, and broken backslope, respectively.

C11.10.5.3

For relatively thick facing elements, it may be desirable to include the facing dimensions and weight in sliding and overturning calculations, i.e., use B in lieu of L as shown in Figure 11.10.5.2-1.

Testing of the foundation soil or the backfill soil should be considered so that less conservative friction angle values than the default minimums could be used to estimate sliding resistance. Test results that could be used for this purpose include laboratory soil shear strength or interface shear testing, or in-situ testing combined with correlations to soil shear strength.

of sliding friction shall be taken as the lesser of ϕ_r , ϕ_f , and ρ , where ρ is the soil-reinforcement interface friction angle. In the absence of specific data, a maximum friction angle, ϕ_f , of 30 degrees, ϕ_r of 34 degrees, and soil-reinforcement interface angle, ρ , of $2/3\phi_f$ or $2/3\phi_r$, should be used.

If the lowest reinforcement layer is above the bottom of the wall facing, to check sliding at the base of the wall, the friction angle of the foundation soil, ϕ_f , or reinforced fill soil, ϕ_r , whichever is less, shall be used to assess sliding resistance. To check sliding resistance at the lowest reinforcement layer in this case, since the reinforcement is fully within the reinforced fill, the interface friction angle, ρ , should be based on the friction angle for the reinforced fill, ϕ_r .

11.10.5.4—Bearing Resistance

For the purpose of computing bearing resistance, an equivalent footing shall be assumed whose length is the length of the wall, and whose width is the length of the reinforcement strip at the foundation level. Bearing pressures shall be computed using a uniform base pressure distribution over an effective width of footing determined in accordance with the provisions of Articles 10.6.3.1 and 10.6.3.2.

Where soft soils or sloping ground in front of the wall are present, the difference in bearing stress calculated for the wall reinforced soil zone relative to the local bearing stress beneath the facing elements shall be considered when evaluating bearing capacity. In both cases, the leveling pad shall be embedded adequately to meet bearing capacity requirements.

11.10.5.5—Overturning

The provisions of Article 11.6.3.3 shall apply.

11.10.5.6—Overall and Compound Stability

The provisions of Article 11.6.3.7 shall apply. Additionally, for MSE walls with complex geometrics,

C11.10.5.4

The effect of eccentricity and load inclination is accommodated by the introduction of an effective width, $B' = L - 2e$, instead of the actual width.

For relatively thick facing elements, it may be reasonable to include the facing dimensions and weight in bearing calculations, i.e., use B in lieu of L as shown in Figure 11.10.2-1.

Note, when the value of eccentricity, e , is negative: $B' = L$.

Due to the flexibility of MSE walls, a triangular pressure distribution at the wall base cannot develop, even if the wall base is founded on rock, as the reinforced soil mass has limited ability to transmit moment. Therefore, an equivalent uniform base pressure distribution is appropriate for MSE walls founded on either soil or rock.

Concentrated bearing stresses from the facing weight on soft soil could create concentrated stresses at the connection between the facing elements and the wall backfill reinforcement.

C11.10.5.5

Reinforced soil walls are in general too flexible to fail due to excessive eccentricity (i.e., overturning). However, meeting the eccentricity requirements for gravity walls specified in Article 11.6.3.3 will keep the reinforced soil wall from being too flexible in its response to lateral earth pressure and other lateral loads that may be present behind the reinforced soil wall. See Article C11.10.2.1 for additional explanation regarding the effect shorter reinforcement length may have on MSE wall flexibility and deformation.

C11.10.5.6

Development of LEA for MSE wall design is summarized in Leshchinsky et al. (2016 and 2017). LEA,

MSE walls on sloping ground (above or below the wall), walls located on soft or otherwise potentially unstable ground, and walls supporting foundation loads located above or just behind the soil reinforcement, compound failure surfaces which pass through a portion of the reinforced soil mass as illustrated in Figure 11.10.5.6-1 shall be investigated. Limit equilibrium analyses shall be used to evaluate compound stability. The long-term strength of each backfill reinforcement layer intersected by the failure surface should be considered as resisting forces in the limit equilibrium slope stability analysis.

For the Limit Equilibrium Analysis (LEA), values of T_{max} for each reinforcement layer crossed by the critical failure surface(s) shall be obtained.

Figure 11.10.5.6-1—Overall and Compound Stability of Complex MSE Wall Systems

To perform a LEA for compound stability, three analysis steps shall be conducted, which are as follows:

1. Estimate the nominal load in each reinforcement layer, T_{max} , targeting a load and resistance factor combination of 1.0.
2. Adjust the reinforcement spacing and strength required to meet the limit states as specified in Articles 11.10.6.3 and 11.10.6.4 for each reinforcement layer using factored load and resistance values. Load factors shall be as specified in Tables 3.4.1-1 and 3.4.1-2, and resistance factors as specified in Table 11.5.7-1 and in Article 11.6.3.7.
3. Check the factored design using LEA with factored load and resistance values.

When additional surcharge loads, such as a structure footing load or live load, are applied to the top of the reinforced zone of the MSE wall, for Step 3, they shall be factored as specified in Article 3.4.1 for the Strength I limit state.

using either a log spiral or circular failure surface, is described by Vahedifard et al. (2014 and 2016) and Leshchinsky et al. (2016 and 2017). Chapters 9 and 10 of FHWA-HIF-17-004 (Leshchinsky et al., 2016) also include detailed procedures and examples for use of LEA to evaluate and design geosynthetic walls. It is also possible to conduct the LEA using conventional slope stability computer software in which the tensile inclusions provide resistance to slope instability.

Note that in complex structures such as multi-tiered walls or high-strength retained soil (e.g., rock), the critical failure surface may reside entirely within the reinforced soil zone (e.g., see Leshchinsky et al., 2016).

LEA should not be used for internal stability design of MSE walls with inextensible (e.g., steel) reinforcement in lieu of empirically based procedures as specified in Article 11.10.6.2.1. Leshchinsky et al. (2016) indicate that inextensible reinforcements do not allow the soil strength to be fully mobilized, forcing the soil reinforcement to take on additional load. Allen and Bathurst (2018) provide a summary of measurements and LEA predictions which confirm these observations. With regard to extensibility of the reinforcement, see Allen and Bathurst (2018) and Leshchinsky et al. (2016) for guidance. However, for compound stability, use of LEA is the only available practical choice for both extensible and inextensible reinforced MSE walls.

For LEA, the resistance available in the wall is equal to the total long-term tensile strength, T_{al} , of the reinforcement layers available or the pullout resistance available at the intersection of each analyzed slip surface and each reinforcement layer, whichever controls the design. However, regarding T_{al} , working loads in geosynthetic reinforced MSE walls are usually low enough that strength loss due to creep is unlikely, since it is typically at the very end of the reinforcement design life that such strength loss occurs.

Geosynthetic MSE walls are generally not designed to stay in a state of limit equilibrium long-term after the wall face deformation becomes excessive, as it would normally be repaired or replaced at that point. Therefore, the reduction factors for creep and durability used for compound stability assessment can be reduced relative to the reduction factors needed for a 75- or 100-year degradation time period, since there should be plenty of warning as the wall approaches a state of limit equilibrium. For example, a durability reduction factor of near 1.0 and a creep reduction factor for the maximum limit equilibrium load of a few years may be sufficient for geosynthetic walls. However, for reinforcement strength loss mechanisms that occur near the beginning of the reinforcement design life or which result in continuous strength reduction throughout the design life, such as installation damage for geosynthetics, the full-strength reduction as specified in Article 11.10.6.4.3 should be applied to the available soil reinforcement tensile strength for compound stability.

For Step 1, a nominal value of T_{max} from the limit equilibrium slope stability analyses is required to conduct

the strength and extreme event limit state analyses. To accomplish this, the LEA must be conducted to obtain reinforcement loads using a factor of safety of 1.0 (i.e., the combination of load and resistance factors is 1.0) to obtain unfactored values of T_{max} . Any external loads, such as due to a foundation, are also left unfactored for this step. These nominal values of T_{max} are then used to assess the spacing and strength of reinforcement required to meet all the limit states in the next two steps.

For Step 2, the LRFD (factored) design is conducted as specified in Articles 11.10.6.3 and 11.10.6.4. If T_{max} obtained in Step 1 does include the effect of the load caused by an external source such as a foundation, factoring T_{max} using γ_{p-EV} will approximate as much as practical the factored load for this step. This design is then checked in Step 3 using a limit equilibrium slope stability design model in which all loads and resistance values are factored. To accomplish this, the wall tensile reinforcement strength and pullout are factored as specified in Table 11.5.7-1, and the limit equilibrium slope stability analysis is conducted targeting a minimum factor of safety which is the reciprocal of the resistance factors specified in Article 11.6.3.7. If additional external loads such as due to a foundation are present, they are factored as specified in Article 3.4.1.

11.10.6—Safety against Structural Failure (Internal Stability)

11.10.6.1—General

Safety against structural failure shall be evaluated with respect to reinforcement rupture, reinforcement pullout behind the active zone, and connection rupture or pullout.

A preliminary estimate of the structural size of the stabilized soil mass may be determined on the basis of reinforcement pullout beyond the active zone, for which resistance is specified in Article 11.10.6.3.

C11.10.6.1

The resistance factors, specified in Article 11.5.7, are consistent with the use of select backfill in the reinforced zone, homogeneously placed and carefully controlled in the field for conformance with Section 7 of the *AASHTO LRFD Bridge Construction Specifications*, and the use of drainage features necessary to keep the wall backfill well drained. The basis for the factors is the successful construction of thousands of structures in accordance with these criteria, and the use of conservative pullout resistance factors representing high confidence limits. Additionally, hundreds of reinforcement peak strain measurements from many well instrumented MSE walls combined with resistance statistics have been used to verify the resistance factors for internal stability for extensible (e.g., geosynthetic) MSE walls. For steel reinforced MSE walls, the calibration work is yet to be completed; therefore, the resistance factors for steel reinforced MSE walls are based on calibration by fitting to past practice.

11.10.6.2—Loading (Internal Stability)

The load in the reinforcement shall be determined at two critical locations: the zone of maximum stress and the connection with the wall face. Potential for reinforcement rupture and pullout are evaluated at the zone of maximum stress, which is assumed to be located at the boundary

C11.10.6.2

Loads carried by the soil reinforcement in mechanically stabilized earth walls are the result of vertical and lateral earth pressures, which exist within the reinforced soil mass, reinforcement extensibility, facing stiffness, wall toe restraint, and the stiffness and strength

between the active zone and the resistant zone in Figure 11.10.2-1. Potential for reinforcement rupture and pullout are also evaluated at the connection of the reinforcement to the wall facing.

The maximum friction angle used for the computation of horizontal force within the reinforced soil mass shall be assumed to be 34 degrees, unless the specific project select backfill is tested for frictional strength by triaxial or direct shear testing methods, AASHTO T 296 and T 297 or T 236, respectively. For internal stability, a design friction angle of greater than 40 degrees shall not be used with any reinforcement load prediction method, even if the measured friction angle is greater than 40 degrees.

of the soil backfill within the reinforced soil mass. The soil reinforcement extensibility and material type are major factors in determining reinforcement load. In general, inextensible reinforcements consist of metallic strips, bar mats, or welded wire mats, whereas extensible reinforcements consist of geotextiles or geogrids, and geostrips. Inextensible reinforcements reach their peak strength at strains lower than the strain required for the soil to reach its peak strength. Extensible reinforcements reach their peak strength at strains greater than the strain required for soil to reach its peak strength. Additional guidelines regarding definition of extensibility are provided in Allen and Bathurst (2018).

Internal stability failure modes include soil reinforcement rupture, reinforcement pullout behind the active zone, and connection rupture or pullout. The service limit state is not evaluated for internal stability design with the exception of the soil failure limit state within the context of the Stiffness Method, as specified in Article 11.10.4.3.

Analysis of full-scale wall data in comparison to the widely accepted design methods such as the Coherent Gravity and Simplified methods (see Article 11.10.6.2.1) indicates that these methods will significantly underestimate reinforcement loads for inextensible steel reinforcement if design soil friction angles greater than 40 degrees are used. This recommendation applies to soil friction angles as determined using triaxial or direct shear tests, as the Simplified and Coherent Gravity methods were calibrated using triaxial or direct shear soil strengths (see Allen et al., 2001).

While it is possible to use a friction angle higher than 40 degrees for MSE walls with extensible reinforcement, long-term practice has been to not use higher friction angles for design for all MSE wall reinforcement types.

11.10.6.2.1—Maximum Reinforcement Loads

Maximum reinforcement loads, T_{max} , in each reinforcement layer shall be calculated using the following methods:

- the Coherent Gravity Method for inextensible (e.g., steel) reinforced MSE walls, and
- the Stiffness Method for extensible (e.g., geosynthetic) reinforced MSE walls.

The Simplified Method, provided in Appendix B11, is also acceptable to use for MSE wall design and applies to both steel and geosynthetic reinforced wall systems, but shall not be considered applicable to walls with a facing batter of greater than 20 degrees from vertical, unless k_a is calculated for a wall face batter of no greater than 20 degrees.

The Coherent Gravity Method shall be applied to walls with inextensible (e.g., steel) soil reinforcement, and shall not be considered applicable to walls with a facing batter of greater than 20 degrees from vertical unless k_a is calculated for a wall face batter of no greater than 20 degrees.

C11.10.6.2.1

The methods outlined in these Specifications for predicting T_{max} are empirically developed from measurements made during wall operational conditions. It is therefore important that these methods be applied to design situations that are within the range of the case history data used to develop them. For insights as to the range of the design situations applicable to the Coherent Gravity Method, see Schlosser (1978), Schlosser and Segrestin (1979), and Allen et al. (2001). Likewise, for the Simplified Method, included in Appendix B11, see Allen et al. (2001). Finally, for the Stiffness Method, see Allen and Bathurst (2015 and 2018). If any of these methods must be used for situations that are significantly beyond their empirical basis, additional evaluations should be considered. Evaluations that should be considered to address internal stability and the determination of T_{max} in such cases include the use of LEA, as described in Article 11.10.5.6, or possibly numerical modeling to assess the effect of the condition that is not within the empirical basis for the methods provided in Article 11.10.6.2.1 on T_{max} for each

11.10.6.2.1a—Special Loading Conditions

Soil surcharges above the reinforced soil wall zone shall be distributed as a uniform surcharge of thickness S within a reinforced wall backfill width of $0.7H$ as shown in Figure 11.10.6.2.1a-1 for the Stiffness and Simplified Methods. Sloping surcharge shall be addressed for the Coherent Gravity Method, as shown in Figure 11.10.6.2.1d-2.

Traffic live loads shall be positioned for extreme force effect. Traffic live load shall be distributed on the wall top as a uniform surcharge, as shown in Figure 11.10.6.2.1a-2. The provisions of Article 3.11.6 shall apply.

Figure 11.10.6.2.1a-1—Calculation of Vertical Stress for Sloping Backslope Condition for Internal Stability Analysis

$$\sigma_2 = S\gamma_f \quad (11.10.6.2.1a-1)$$

where:

S = average height of soil surcharge within $0.7H$ of back of wall face (ft)

γ_f = unit weight of soil surcharge (lbs/ft³)

For sloping surcharge:

$$S = (0.5)(0.7H) \tan \beta \quad (11.10.6.2.1a-2)$$

For an irregular surcharge slope, S = area of surcharge within $0.7H$, divided by $0.7H$.

Note: H is the total height of the wall at the face. Z is referenced from the top of the wall where the backfill intersects the back of wall facing.

C11.10.6.2.1a

Sloping soil surcharges are taken into account through an equivalent uniform surcharge and assuming a level backslope condition. For these calculations, the depth, Z , is referenced from the top of the wall at the wall face, excluding any copings and appurtenances.

Note that T_{max} , the tensile load in the soil reinforcement, is calculated twice for internal stability design as follows: (1) for checking reinforcement and connection rupture, determine T_{max} with live load surcharge included in the calculation of σ_v ; (2) for checking pullout, determine T_{max} with live load surcharge excluded from the calculation of σ_v .

Figure 11.10.6.2.1a-2—Calculation of Vertical Stress for Horizontal Backslope Condition, Including Live Load

Additional vertical surcharge loads (e.g., due to structure foundations) as well as horizontal loads that must be resisted by the soil reinforcement shall be added to the lateral earth pressure due to reinforced soil backfill self-weight using superposition principles as specified in Article 11.10.10.

11.10.6.2.1b—Reinforcement Spacing for Calculation of T_{max}

For uniform vertical spacing of soil reinforcement, S_v , the tributary layer thickness, is equal to the vertical spacing of the reinforcement. For nonuniform vertical spacing of soil reinforcement, S_v , shall be taken as shown in Figure 11.10.6.2.1b-1.

A tributary layer thickness, S_v , greater than 2.7 ft should not be used without full-scale wall data (e.g., reinforcement loads and strains, and overall deflections) that support the acceptability of larger vertical spacing, except for MSE wall systems with facing units equal to or greater than 2.7 ft high with a minimum facing unit width, W_u , equal to or greater than the facing unit height. For these larger facing units the maximum spacing, S_v , shall not exceed the width of the facing unit, W_u , or 3.3 ft, whichever is less.

C11.10.6.2.1b

The design specifications provided herein assume that the wall facing combined with the reinforced backfill acts as a coherent unit to form a gravity retaining structure. Research by Allen et al. (2003) and Allen and Bathurst (2018) indicates that reinforcement loads increase linearly with increasing reinforcement spacing to a reinforcement vertical spacing of 2.7 ft or more, though a vertical spacing of this magnitude should not be attempted unless the facing is considered to be adequately stiff to prevent excessive bulging between layers (see Article C11.10.2.3.2).

In Figure 11.10.6.2.1b-1, not all reinforcement layers are shown, and this figure is only for illustrating concepts. Note that S_v at the top of the wall for the first reinforcement layer is based on the level backfill case whether or not a sloping surcharge is present.

Figure 11.10.6.2.1b-1—Determination of the Tributary Layer Thickness, S_v

Horizontal spacing of reinforcement elements should not exceed 3.3 ft for walls with rigid facing panels. For walls with flexible facing panels, smaller horizontal gaps between soil reinforcement elements should be considered. Horizontal gaps between reinforcement elements shall be limited such that yielding of the steel, both in the facing and the soil reinforcement, and excessive deformation in the facing panels is prevented.

Regarding horizontal spacing of reinforcement elements, spacing as large as 3.3 ft has been used in typical design and construction practice for MSE walls. Back-analysis of instrumented MSE walls indicates that reinforcement load prediction accuracy is not adversely compromised with horizontal spacing of this magnitude when the reinforcement elements are directly attached to rigid facings such as precast concrete panels. However, for flexible facings such as welded wire, large horizontal spacing of the reinforcement has been shown to cause poor wall performance, such as excessive deformation and local yielding of the steel in either the facing element or the soil reinforcement, or both. Therefore, if horizontal gaps of this magnitude are used, the effect of the gaps on the facing panel deformation and stress in the steel should be investigated. See Article C11.10.4.2 for the definition of excessive deformation. With regard to steel stress, the stress level should be below yield both in the short term and long term.

11.10.6.2.1c—Calculation of Lateral Earth Pressure Coefficients for Determination of T_{max}

k_a shall be determined using Eq. 3.11.5.3-1, assuming no wall friction and level backfill slope (i.e., $\delta = \beta$ and $\beta = 0$) for the empirically developed methods (e.g., the Coherent Gravity and Stiffness methods).

k_o shall be determined using Eq. 3.11.5.2-1.

C11.10.6.2.1c

The assumption of no wall friction and level backfill slope (i.e., $\delta = \beta$ and $\beta = 0$) is consistent with the empirical development of the Simplified, Coherent Gravity, and Stiffness methods for estimating T_{max} in each reinforcement layer. Since the Limit Equilibrium Method is theoretical (i.e., not empirically calibrated), it does not necessarily have these restrictions.

Since it is assumed for internal stability of MSE walls that $\delta = \beta$, and β is assumed to always be zero for internal stability, for a vertical wall, the Coulomb equation simplifies mathematically to the simplest form of the Rankine equation.

$$k_a = \tan^2 \left(45 - \frac{\phi'_f}{2} \right) \quad (\text{C11.10.6.2.1c-1})$$

If the wall face is battered, the following simplified form of the Coulomb equation may be used for the Coherent Gravity Method:

$$k_a = \frac{\sin^2(\theta + \phi'_f)}{\sin^3 \theta \left(1 + \frac{\sin \phi'_f}{\sin \theta} \right)^2} \quad (\text{C11.10.6.2.1c-2})$$

with variables as defined in Figure 3.11.5.3-1.

11.10.6.2.1d—Coherent Gravity Method

The Coherent Gravity Method shall be applied to inextensible (e.g., steel) soil reinforcement systems. The Coherent Gravity Method should be not used for walls with cohesive backfill (i.e., soil with a plastic index greater than 6).

For steel-reinforced wall systems, the lateral earth pressure coefficient used shall be equal to k_o at the point of intersection of the theoretical failure surface with the ground surface at or above the wall top, transitioning to k_a at a depth of 20.0 ft below that intersection point, and constant at k_a at depths greater than 20.0 ft as illustrated in Figure 11.10.6.2.1d-1.

For the Coherent Gravity Method, the reinforced wall mass is treated as a rigid body. Vertical stress shall be calculated at each reinforcement level using an equivalent uniform pressure that accounts for load eccentricity caused by the lateral earth pressure acting at the back of the reinforced soil mass above the reinforcement level being considered. This base pressure shall be applied over an effective width of reinforced wall mass as shown in Figure 11.10.6.2.1d-2. Live load should not be included in the vertical stress calculation to determine T_{max} for assessing pullout loads when using the Coherent Gravity Method, but live load is included in the vertical stress calculation for assessing the needed reinforcement strength.

The calculation of T_{max} using the Coherent Gravity Method is summarized in Eqs. 11.10.6.2.1d-1 through 11.10.6.2.1d-4, and Figures 11.10.6.2.1d-1 and 11.10.6.2.1d-2, as follows:

$$T_{max} = S_v k_r \sigma_v \quad (11.10.6.2.1d-1)$$

$$\sigma_v = \frac{V_1 + V_2 + F_r \sin \beta}{L - 2e} \quad (11.10.6.2.1d-2)$$

C11.10.6.2.1d

See Allen, et al. (2001) for additional information regarding the Coherent Gravity Method, including comparisons to measured reinforcement loads and vertical stresses in a number of instrumented full-scale walls. See NCHRP Report 290 (Mitchell and Villet, 1987) for some example problems using this method.

For design situations that are beyond the empirical basis for this method, see Article C11.10.6.2.1 for additional evaluations that should be considered.

Figure 11.10.6.2.1d-2—Forces and stresses for Calculating Meyerhof Vertical Stress Distribution in MSE Walls

For more complex MSE wall loading situations, reinforcement loads shall be calculated as specified in Articles 11.10.10 and 11.10.11, accounting for the eccentricity of each load and its effect on T_{max} for each layer.

11.10.6.2.1e—Stiffness Method

The Stiffness Method shall be applied to extensible (e.g., geosynthetics such as geotextiles, geogrids, and geostrips) soil reinforcement in MSE systems. Prevention of soil failure (service limit state) as specified in Article 11.10.4.3 shall be assessed when using this method.

T_{max} shall be determined as follows using the Stiffness Method:

$$T_{max} = S_v \left[H \gamma_r D_{tmax} + \gamma_f \left(\frac{H_{ref}}{H} \right) S \right] k_{avh} \Phi \quad (11.10.6.2.1e-1)$$

where:

- S_v = tributary vertical thickness for reinforcement layer (ft)
- H = height of wall (ft)
- H_{ref} = reference wall height = 20.0 ft
- γ_r = unit weight of soil in wall reinforcement zone (lbs/ft³)
- S = average soil surcharge thickness over reinforcement (ft)
- γ_f = unit weight of soil in wall in surcharge above wall (kips/ft³)
- D_{tmax} = T_{max} distribution factor (dim.)

C11.10.6.2.1e

As is true of the Coherent Gravity Method, the Stiffness Method was developed empirically to estimate MSE wall soil reinforcement loads at operational conditions. Therefore, it is necessary to make sure that the strains in the reinforcement are not large enough to allow a shear surface to fully develop through the reinforced wall backfill. Since the Stiffness Method, especially for relatively extensible soil reinforcement, provides a less conservative estimate of reinforcement loads, ensuring that the soil failure (service limit state) is not reached or exceeded as specified in Article 11.10.4.3 is an important component of this method.

For design situations that are beyond the empirical basis for this method, see Article C11.10.6.2.1 for additional evaluations that should be considered.

This method does not calculate the vertical stress at each reinforcement level as is done in the Coherent Gravity (Article 11.10.6.2.1d) and Simplified (Appendix B11) methods. Instead, the vertical stress at the base of the wall is calculated (i.e., equal to $H\gamma_r$ if no soil surcharge is present), multiplied by k_{avh} using Eq. C11.10.6.2.1c-1, and is distributed to each reinforcement layer using an empirical T_{max} distribution factor, D_{tmax} . Note that the facing batter is not taken into account using the active earth pressure coefficient directly, but instead is taken into account through the facing batter factor. Additional loads in the reinforcement, such as due to a sloping soil

- k_{avh} = active earth pressure coefficient for a wall with a vertical face (dim.)
- Φ = empirically determined influence factor that captures the effect that the soil reinforcement properties, soil cohesion, and wall geometry have on T_{max} (dim.)

D_{tmax} shall be determined as follows:

For $Z < z_b$:

$$D_{tmax} = D_{tmax0} + \left(\frac{Z}{z_b} \right) (1 - D_{tmax0}) \quad (11.10.6.2.1e-2)$$

For $z \geq z_b$: $D_{tmax} = 1.0$

$$z_b = C_h (H)^{1.2} \quad (11.10.6.2.1e-3)$$

where:

- Z = depth of reinforcement layer below top of wall at wall face (ft)
- z_b = depth below top of wall at wall face where D_{tmax} becomes equal to 1.0 (and below which D_{tmax} equals 1.0) (ft)
- D_{tmax0} = T_{max} distribution factor magnitude at top of wall at wall face, equal to 0.12 (dim.)
- C_h = coefficient equal to 0.32 when H is in ft and 0.40 when H is in meters

For vertical or near-vertical walls (i.e., a facing batter of 10 degrees or less from the vertical) with a single reinforcement strength and stiffness, and cohesionless backfill soil (defined as having a plasticity index of 6 or less), Φ shall be determined as follows:

$$\Phi = \Phi_g \Phi_{fs} \quad (11.10.6.2.1e-4)$$

where:

- Φ_g = global stiffness factor (dim.)
- Φ_{fs} = facing stiffness factor

The global stiffness factor shall be determined as follows:

$$\Phi_g = 0.16 \left(\frac{S_{global}}{P_a} \right)^{0.26} \quad (11.10.6.2.1e-5)$$

where:

- S_{global} = global reinforcement stiffness (ksf)
- P_a = atmospheric pressure at sea level (equals 2.11 ksf)

and,

surcharge, are added to each reinforcement layer using a superposition principle. For a sloping or broken back soil surcharge above the wall, the average surcharge height, S , as defined in Article 11.10.6.2.1 is multiplied by the soil surcharge unit weight, and is then adjusted for its influence on T_{max} based on H_{ref}/H . This adjustment is greater than 1.0 if the wall height is less than H_{ref} (i.e., short stubby walls) and is less than 1.0 for taller walls. Hence, the taller the wall, the less the soil surcharge influences the T_{max} values. For concentrated surcharge loads such as due to a structure footing, using superposition, Articles 3.11.6.3, 3.11.6.4, 11.10.10, and 11.10.11 apply, in which the additional lateral stress over the reinforcement layer tributary area is conservatively added directly to T_{max} . Similarly, for seismic loads for internal stability design, Article 11.10.7.2 applies, in which the additional lateral stress over the tributary area for each reinforcement layer or element is conservatively added directly to T_{max} by superposition.

Determination of the T_{max} distribution factor, D_{tmax} , is illustrated in Figure C11.10.6.2.1e-1. In the figure, depths below the wall top have been normalized by the wall height, H . T_{maxmx} is the maximum value of T_{max} in the wall section.

Figure C11.10.6.2.1e-1—Illustration of D_{tmax} Factor

Eqs. 11.10.6.2.1e-1 through 11.10.6.2.1e-6 are a simplified version of the complete Stiffness Method. The complete Stiffness Method contains additional influence factors to account for facing batter, Φ_{fb} , variations in the stiffness of the reinforcement within the wall cross-section, Φ_{local} , and soil cohesion, Φ_c . The complete Stiffness Method and its application to MSE wall internal stability design is provided in Allen and Bathurst (2015 and 2018). The Supplemental Materials for Allen and Bathurst (2018) also include detailed step-by-step procedures and

$$S_{\text{global}} = \frac{J_{\text{ave}}}{(H/n)} = \frac{\sum_{i=1}^n J_i}{H} \quad (11.10.6.2.1e-6)$$

where:

- J_{ave} = average secant tensile stiffness of all n reinforcement layers (kips/ft)
 J_i = secant tensile stiffness of reinforcement layer i considering the horizontal spacing, i.e., the coverage ratio R_c , of the reinforcement (kips/ft)
 n = number of reinforcement layers in wall section (dim.)

For discontinuous reinforcement, the reinforcement coverage ratio shall be determined as specified in Article 11.10.6.4.1.

For geogrids and geotextiles, the reinforcement stiffness should be based on the laboratory secant creep stiffness at 2 percent strain and 1,000 hours as specified in AASHTO R 69.

For a flexible faced wall with extensible reinforcement (e.g., geosynthetics), set $\Phi_{fs} = 1$.

If the wall is tall enough such that layers with different strength and stiffness properties are needed to match the layer strengths to the layer specific T_{max} values, the complete Stiffness Method equation described in Article C11.10.6.2.1 should be used.

If the MSE wall internal stability design using this method results in the reinforcement strength required to be near or below the strength of the weakest geosynthetic reinforcement products available, the maximum reinforcement spacing requirements, both in the vertical and horizontal direction, specified in Articles 11.10.2.3.1 and 11.10.6.2.1b, and the minimum installation damage resistance specified in Article 11.10.6.4.2b, shall still be met.

examples of how to use the method for LRFD internal stability design of MSE walls. The complete method should be used if the wall face is significantly battered or stepped (i.e., a facing batter of 10 degrees or more from the vertical), for geosynthetic walls in which the wall facing is flexible and the reinforcement layer stiffness values vary significantly within the wall section, and for walls which have a stiff facing.

It is assumed that the wall backfill meeting the requirements in Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications* is noncohesive (i.e., PI less than or equal to 6 and a fines content of less than 15 percent). If any cohesion is present for soil that meets these PI and percent fines content requirements, it should be assumed that this cohesion will be lost at some point during the wall design life. Since no cohesion is assumed for determination of T_{max} , the cohesion influence factor, Φ_c , in the complete Stiffness Method in Allen and Bathurst (2015 and 2018) should be assumed equal to 1.0. See Allen and Bathurst (2018) for additional guidance regarding the effect of long-term changes in soil cohesion and its potential post-construction effect on wall face deformation and reinforcement loading.

For geostrip walls, working strains tend to be lower than for other geosynthetics based on strain measurements observed in full scale geostrip walls (Miyata et al., 2018), and J_i determined at a strain level of 1 percent may be more appropriate.

A comparison between the Simplified Method and the complete Stiffness Method, not including traffic surcharge load, is provided in Figure C11.10.6.2.1e-2. Essentially, the Stiffness Method was developed by starting with the Simplified Method, correcting the T_{max} distribution to more accurately reflect measurements in full-scale structures, and replacing the semi-empirical (k_r/k_a) term with a reinforcement stiffness-based term calibrated to measurements in full-scale structures.

Figure C11.10.6.2.1e-2—Comparison of AASHTO Simplified and Stiffness Method Equations (Allen and Bathurst 2015)

Facing stiffness factor, Φ_{fs} , could also be conservatively set to 1.0 for tall geosynthetic walls (i.e., $H > 10$ m) and for typical “thin” panel-face systems, such as incremental concrete panels. For geosynthetic reinforcement and a stiff facing, Φ_{fs} should be determined as described in Allen and Bathurst (2015 and 2018).

Alternatively, Φ_{fs} in that case may conservatively be assumed to be equal to 1.0.

For full height and incremental panel walls, $h_{eff} = H$ and panel height, respectively. Since the facing stiffness factor, Φ_{fs} , is intended to be a single value for the wall, a single representative value of h_{eff} must be selected. Typically, h_{eff} is set equal to the reinforcement vertical spacing in modular block-type structures since the reinforcement is located at the horizontal joints between facing units. For blocks that do not have a reinforcement layer at the horizontal joints, these facings will have better interlock and moment transfer from block to block. If the reinforcement spacing is nonuniform, the smallest predominate spacing should be used for this calculation. Smaller h_{eff} values will lead to more conservative design because the facing stiffness factor will be larger. For two-stage walls in which the outer facing is built after the wall is built to full height, the facing stiffness factor should be based on the facing stiffness of the first stage wall (typically the first stage wall face is flexible, and the facing stiffness factor is 1.0 in that case).

It is possible that, especially for shorter walls, the strength required using this method could be at or below the weakest geosynthetic reinforcement products available. In such cases it is important to:

- keep the reinforcement spacing, both vertically and horizontally, within the maximum limits specified in Articles 11.10.2.3.1 and C11.10.6.2.1b;
- keep the reinforcement strong enough such that installation damage does not become excessive, as defined in Article 11.10.6.4.2b and C11.10.6.4.2b.

In such cases it may be necessary to use reinforcement that is stronger than the minimum strength required when using this T_{max} prediction method.

11.10.6.2.2—Reinforcement Loads at Connection to Wall Face

The nominal tensile load applied to the soil reinforcement connection at the wall face, T_o , shall be equal to the nominal reinforcement tension, T_{max} , for all wall systems regardless of facing and reinforcement type.

11.10.6.3—Reinforcement Pullout

11.10.6.3.1—Boundary between Active and Resistant Zones

The location of the zone of maximum stress for inextensible and extensible wall systems, i.e., the boundary between the active and resistant zones, is determined as shown in Figure 11.10.6.3.1-1. For all wall systems, the zone of maximum stress shall be assumed to begin at the back of the facing elements at the toe of the wall.

For extensible wall systems with a face batter of less than ten degrees from the vertical, the zone of maximum

stress should be determined using the Rankine method. Since the Rankine method cannot account for wall face batter or the effect of concentrated surcharge loads above the reinforced backfill zone, the Coulomb method shall be used for walls with extensible reinforcement in cases of significant batter, defined as ten degrees from vertical or more, and concentrated surcharge loads to determine the location of the zone of maximum stress.

(a) Inextensible Reinforcements

(b) Extensible Reinforcements

Figure 11.10.6.3.1-1—Location of Potential Failure Surface for Internal Stability Design of MSE Walls

For walls with a face batter 10 degrees or more from the vertical,

$$\tan(\Psi - \phi_r) = \frac{-\tan(\phi_r - \beta) + \sqrt{\tan(\phi_r - \beta) [\tan(\phi_r - \beta) + \cot(\phi_r + \theta - 90)] [1 + \tan(\delta + 90 - \theta) \cot(\phi_r + \theta - 90)]}}{1 + \tan(\delta + 90 - \theta) [\tan(\phi_r - \beta) + \cot(\phi_r + \theta - 90)]}$$

with $\delta = \beta$ and all other variables defined in Figure 3.11.5.3-1.

11.10.6.3.2—Reinforcement Pullout Design

C11.10.6.3.2

The reinforcement pullout resistance shall be checked at each level against pullout failure. Only the effective pullout length which extends beyond the theoretical failure surfaces in Figure 11.10.6.3.1-1 shall be used in this calculation. A minimum length, L_e , in the resistant zone of 3.0 ft shall be used. The total length of reinforcement required for pullout is equal to $L_a + L_e$ as shown in Figure 11.10.6.3.1-1.

Note that traffic loads applied as a uniform surcharge are neglected in pullout calculations (see Figure 11.10.6.2.1a-2). Lateral traffic impact loads, such as through a traffic barrier, however, should not be neglected.

The effective pullout length shall be determined using the following equation:

$$L_e \geq \frac{\gamma_{p-EV} T_{max}}{\phi F^* \alpha \sigma_v C R_c} \quad (11.10.6.3.2-1)$$

$F^* \alpha \sigma_v C R_c$ is the ultimate pullout resistance, P_r , per unit of reinforcement width.

where:

- L_e = length of reinforcement in resisting zone (ft)
- T_{max} = applied load in the reinforcement from Article 11.10.6.2.1 (kips/ft)
- γ_{p-EV} = load factor for vertical earth pressure, EV , specified in Table 3.4.1-2 (dim.)
- ϕ = resistance factor for reinforcement pullout from Table 11.5.7-1 (dim.)
- F^* = pullout friction factor (dim.)
- α = scale effect correction factor (dim.)
- σ_v = unfactored vertical stress at the reinforcement level in the resistant zone (ksf)
- C = overall reinforcement surface area geometry factor based on the gross perimeter of the reinforcement and is equal to 2 for strip, grid and sheet-type reinforcements, i.e., two sides (dim.)
- R_c = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)

The vertical stress, σ_v , used to calculate pullout resistance shall be determined as shown in Figure 11.10.6.2.1a-2 for the horizontal backslope condition and in Figure 11.10.6.3.2-1 for the sloping backslope condition.

For more complex loading situations, such as due to the presence of traffic impact load or concentrated loads due to foundations located on top of or within the reinforced soil, Eq. 11.10.6.3.2-1 shall be modified to accommodate the load combination, replacing $\gamma_{p-EV} T_{max}$ with T_{total} as calculated in Eq. 11.10.10.1-1, when concentrated foundation loads are present. When traffic impact loads (i.e., as applied through a traffic barrier) are present, pullout design shall include the additional transient load as specified in Article 11.10.10.2.

Since the traffic impact load is applied near the back of the wall face, the full length of the reinforcement behind the wall face could be used to calculate pullout resistance to the load increase caused by the impact load, as recommended by Bligh et al. (2010).

Nominal Vertical Confining Pressure:

$$\sigma_1 = \gamma_r Z$$

$$\sigma_2 = \gamma_f (Z_p - Z) \text{ for sloping backfill}$$

$$\sigma_{v-po} = \gamma_r Z + \gamma_f (Z_p - Z)$$

$$Z_p = Z + \left(L_a + \left(\frac{1}{2} \right) L_e \right) \tan \beta \text{ for sloping backfill}$$

Figure 11.10.6.3.2-1—Vertical Confining Pressure and Z_p Depth in Resistant Zone beneath Sloping Backfill

F^* and α shall be determined from product-specific pullout tests in the project backfill material or equivalent soil, or they can be estimated empirically/theoretically.

For standard backfill materials (see Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*), with the exception of uniform sands, i.e., coefficient of uniformity $C_u = D_{60}/D_{10} < 4$, in the absence of test data it is acceptable to use conservative default values for F^* and α as shown in Figure 11.10.6.3.2-2 and Table 11.10.6.3.2-1. For ribbed steel strips, if the specific C_u for the wall backfill is unknown at the time of design, a C_u of 4.0 should be assumed for design to determine F^* .

Table 11.10.6.3.2-1—Default Values for the Scale Effect Correction Factor, α

Reinforcement Type	Default Value for α
All Steel Reinforcements	1.0
Geogrids and Geostrips	0.8
Geotextiles	0.6

The scale effect correction factor α shall be no greater than 1.0.

For grids, the spacing between transverse grid elements, S_t , shall be uniform throughout the length of the

Pullout testing and interpretation procedures (and direct shear testing for some parameters), as well as typical empirical data, are provided in Appendix B of FHWA-NHI-10-025 (Berg et al., 2009).

Recent experience with pullout test results on new geogrids coming into the market has indicated that some materials have pullout values that are lower than the previous F^* default value of $0.8 \tan \phi$. Data obtained by D'Appolonia (1999) also indicate that $0.8 \tan \phi$ is closer to a mean value rather than a default lower bound value for geogrids. The default values for other reinforcement types shown in Figure 11.10.6.3.2-2 are more representative of lower bound values. Therefore, the F^* default value for geosynthetics, including geogrids, geotextiles, and geostrips, has thus been lowered to a more conservative value of $0.67 \tan \phi$ in consideration of these results.

Product-specific pullout testing, if conducted, may not necessarily result in lower bound values of F^* and α . In this case, the resistance factors for pullout specified in Table 11.5.7-1 may need to be reduced to provide the same level of safety implied by the specified resistance factors and default lower bound pullout parameters.

For F^* values based on product- and soil-specific test data, the value of F^* at a depth of 20.0 ft or more should

reinforcement rather than having transverse grid members concentrated only in the resistant zone.

be limited to $\tan \phi_r$, unless the reinforcement geometry can provide significant passive resistance in addition to interface shear. To assess the potential for significant passive resistance during product- and soil-specific pullout testing, the maximum displacement should be limited to 0.75 in. to determine F^* .

F^* for ladder strips, defined as a combination of longitudinal and transverse wires welded together to form a reinforcement strip structure of limited width resembling a ladder, should be determined through product-specific testing. Ladder strips can behave in much the same way as ribbed steel strips if the spacing of the transverse wires or bars is sufficiently frequent. For greater transverse wire or bar spacing, the behavior of ladder strips may instead resemble steel grids. Product-specific testing is needed to determine how the ladder strip behaves in pullout. Regarding the effective width of ladder strips, the entire length of the transverse wire or bar may contribute to the pullout resistance, depending on the length of the protrusions beyond the longitudinal members and the stiffness of the protrusions. This also should be verified through product-specific testing.

For the case when geogrids are cut into strips, the portion of the transverse geogrid members that protrude beyond the outside longitudinal members in the strip should not be considered to contribute to the effective reinforcement width and pullout resistance, due to the flexibility of the transverse geogrid elements.

Figure 11.10.6.3.2-2—Default Values for the Pullout Friction Factor, F^*

These pullout calculations assume that the factored long-term strength of the reinforcement (see Article 11.10.6.4.1) in the resistant zone is greater than T_{max} .

11.10.6.4—Reinforcement Strength

11.10.6.4.1—General

The reinforcement strength shall be checked at every level within the wall, both at the boundary between the active and resistant zones (i.e., zone of maximum stress), and at the connection of the reinforcement to the wall face, for applicable strength limit states as follows:

C11.10.6.4.1

The load factor, γ_{EV} , should be applied to the calculated value of T_{max} . This applies to all methods used to calculate T_{max} with regard to soil self-weight of the reinforced soil volume, as well as soil surcharges (sloping or level) placed above the reinforced soil volume.

At the zone of maximum stress:

$$\gamma_{p-EV} T_{max} \leq \phi T_{at} R_c \quad (11.10.6.4.1-1)$$

where:

- T_{max} = applied load to the reinforcement, determined as specified in Article 11.10.6.2.1 (kips/ft)
- γ_{p-EV} = load factor for vertical earth pressure, *EV*, specified in Table 3.4.1-2 (dim.)
- ϕ = resistance factor for reinforcement tension, specified in Table 11.5.7-1 (dim.)
- T_{at} = nominal long-term reinforcement strength (kips/ft)
- R_c = reinforcement coverage ratio, as defined in Figures 11.10.6.4.1-1 and 11.10.6.4.1-2 (dim.)

T_{at} shall be determined as specified in Article 11.10.6.4.3a for steel reinforcement and Article 11.10.6.4.3b for geosynthetic reinforcement.

When live load is present and treated as an additional uniform surcharge as specified in Article 3.11.6.4, the difference in the load factor used for live load surcharge, *LS*, versus that used for the self-weight of the reinforced backfill, *EV*, shall be recognized when applying load factors to T_{max} to determine the factored reinforcement load.

For more complex loading situations, such as due to the presence of concentrated loads due to foundations located on top of or within the reinforced soil and traffic barrier impact forces, determine T_{max} as specified in Article 11.10.10. Eq. 11.10.6.4.1-1 shall be modified to accommodate the load combination using superposition, replacing $\gamma_{p-EV} T_{max}$ with T_{total} as calculated in Eq. 11.10.10.1-1. When traffic impact loads (i.e., as applied through a traffic barrier) are present, reinforcement strength design shall include the additional transient load as specified in Article 11.10.10.2.

At the connection with the wall face:

$$\gamma_{p-EV} T_o \leq \phi T_{ac} R_c \quad (11.10.6.4.1-2)$$

where:

- T_o = applied load at reinforcement/facing connection specified in Article 11.10.6.2.2 (kips/ft)
- γ_{p-EV} = load factor for vertical earth pressure, *EV*, specified in Table 3.4.1-2 (dim.)
- ϕ = resistance factor for reinforcement tension in connectors specified in Table 11.5.7-1 (dim.)

In past design practice, live load surcharge (load factor is γ_{LS}) is usually included in the calculation of the vertical stress acting at the reinforcement level as a uniform soil surcharge. However, since the load factor applied to *LS* is different in magnitude than the load factor applied to soil self-weight (i.e., 1.75 versus 1.35, respectively), the live load surcharge contribution to T_{max} is calculated and factored separately from the soil self-weight contribution to T_{max} .

E_s = sacrificial thickness of metal expected to be lost by uniform corrosion during service life of structure (mil.)

For structural design, sacrificial thicknesses shall be computed for each exposed surface as follows, assuming that the soil backfill used is nonaggressive:

- Loss of galvanizing = 0.58 mil./yr for first 2 years
= 0.16 mil./yr for subsequent years
- Loss of carbon steel = 0.47 mil./yr after zinc depletion

These metal loss rates shall be considered applicable to hot-dip galvanized steel and not applicable to black steel or steel coated by any other process. Other carbon steel loss rates shall be used for black steel and for steel coated by any other material or process.

Soils shall typically be considered nonaggressive if they meet the following criteria:

- pH = 5 to 10
- Resistivity ≥ 3000 ohm-cm
- Chlorides ≤ 100 ppm
- Sulfates ≤ 200 ppm
- Organic Content ≤ 1 percent

If the resistivity is greater than or equal to 5000 ohm-cm, the chlorides and sulfates requirements may be waived. For bar mat or grid-type reinforcements, the sacrificial thickness listed above shall be applied to the radius of the wire or bar when computing the cross-sectional area of the steel remaining after corrosion losses.

Transverse and longitudinal grid members shall be sized in accordance with ASTM A185. The transverse wire diameter shall be less than or equal to the longitudinal wire diameter.

Galvanized coatings shall be a minimum of 2 oz/ft² or 3.4 mils in thickness, applied in conformance to AASHTO M 111M/M 111 (ASTM A123/A123M).

These sacrificial thicknesses account for potential pitting mechanisms and much of the uncertainty due to data scatter, and are considered to be maximum anticipated losses for soils which are defined as nonaggressive.

Recommended test methods for soil chemical property determination include AASHTO T 289 for pH, AASHTO T 288 for resistivity, AASHTO T 291 for chlorides, AASHTO T 290 for sulfates, and AASHTO T 267 for organic content. The organic content limit of 1 percent is based on the total soil fraction.

Resistivity at saturation is the basis for the sacrificial thicknesses specified in this Article. Resistivity should be determined under the most adverse condition (i.e., a saturated state) in order to obtain a resistivity that is independent of seasonal and other variations in soil-moisture content (Elias et al., 2009).

These sacrificial thickness requirements are not applicable for soils which do not meet one or more of the nonaggressive soil criteria. Additionally, these sacrificial thickness requirements are not applicable in applications where:

- the MSE wall will be exposed to a marine or other chloride-rich environment,
- the MSE wall has a metallic or wire mesh facing, or the metallic soil reinforcement is continuous, forming an electrically conductive circuit along the wall length, and the wall will be exposed to stray currents such as from nearby underground power lines or adjacent electric railways,
- the backfill material is aggressive, or
- the galvanizing thickness is less than specified in these guidelines.

Each of these situations creates a special set of conditions which should be specifically analyzed by a corrosion specialist. Alternatively, noncorrosive reinforcing elements can be considered. Furthermore, these corrosion rates do not apply to other metals. The use of alloys such as aluminum and stainless steel is not recommended.

Requiring the transverse wire diameter to be less than or equal to the longitudinal wire diameter will preclude local overstressing of the longitudinal wires.

The specified minimum thickness of 3.4 mils is more stringent than the minimum requirements in AASHTO M 111M/M 111 (ASTM A123/A123M).

Corrosion-resistant coatings should generally be limited to galvanization. Hot-dip galvanization should be applied after fabrication of the reinforcement into its final configuration.

There is insufficient evidence at this time regarding the long-term performance of epoxy coatings for these

11.10.6.4.2b—Geosynthetic Reinforcements

The long-term strength of geosynthetic reinforcement shall be assessed with consideration to strength losses that occur during installation, and long-term losses due to creep and chemical degradation. The long-term strength of the geosynthetic reinforcement as calculated in accordance with Article 11.10.6.4.3b shall be determined in accordance with AASHTO R 69.

Soil and Related Environmental Requirements: Environmental conditions within the wall shall be assessed considering soil pH, gradation, plasticity, organic content, and in-ground temperature. These conditions shall be considered to be nonaggressive if the following criteria are met:

- pH, as determined by AASHTO T 289, equals 4.5 to 9 for permanent applications and 3 to 10 for temporary applications,
- Maximum soil particle size is less than 0.75 in., unless full-scale installation damage tests are conducted in accordance with AASHTO R 69 and the reduction factor for installation damage, RF_{ID} , is less than or equal to 1.7,
- Soil organic content, as determined by AASHTO T 267 for material finer than the 0.075 in. (No. 10) sieve ≤ 1 percent, and

- Design temperature at wall site:
 - $\leq 86^{\circ}\text{F}$ for permanent applications
 - $\leq 95^{\circ}\text{F}$ for temporary applications

Soil backfill not meeting these requirements shall be considered to be aggressive. The environment at the face, in addition to that within the wall backfill, shall be evaluated, especially if the stability of the facing is dependent on the strength of the geosynthetic at the face, i.e., the geosynthetic reinforcement forms the primary connection between the body of the wall and the facing.

The chemical properties of the native soil surrounding the mechanically stabilized soil backfill shall

coatings to be considered equivalent to galvanizing. If epoxy-type coatings are used, they should meet the requirements of ASTM A884 for bar mat and grid reinforcements, or ASTM A775/A775M for strip reinforcements, and have a minimum thickness of 16 mils.

C11.10.6.4.2b

The durability of geosynthetic reinforcement is influenced by environmental factors such as time, temperature, mechanical damage, stress levels and chemical exposure, e.g., oxygen, water, and pH, which are the most common chemical factors. Microbiological attack may also affect certain polymers, although not most polymers used for carrying load in soil reinforcement applications. The effects of these factors on product durability are dependent on the polymer type used, i.e., resin type, grade, additives, and manufacturing process, and the macrostructure of the reinforcement. Not all of these factors will have a significant effect on all geosynthetic products. Therefore, the response of geosynthetic reinforcements to these long-term environmental factors is product-specific.

While soil plasticity is not specifically included in the specified wall environment criteria, soils with significant plasticity are more likely to have properties that could have an adverse effect on the long-term performance of the geosynthetic reinforcement. In general for MSE walls, Article 7.3.6.3 of the *AASHTO LRFD Bridge Construction Specifications*, requires that MSE wall soil backfill have no more than 15 percent fines and a PI as determined by AASHTO T 90 of no more than 6. For backfill soil that does not meet these requirements, soil-specific studies to investigate the effect the soil may have on the long-term performance of the geosynthetic reinforcement should be considered.

See Bathurst et al. (2011) for additional information on the reason for keeping RF_{ID} at or below 1.7, in which they indicate that when RF_{ID} is greater than 1.7, the variability in the as-installed tensile strength increases significantly. The current resistance factor for reinforcement rupture of geosynthetics may not adequately account for this increased variability.

The effective design temperature is defined as the temperature which is halfway between the average yearly air temperature and the normal daily air temperature for the warmest month at the wall site. Note that for walls which face the sun, it is possible that the temperature immediately behind the facing could be higher than the air temperature. This condition should be considered when assessing the design temperature, especially for wall sites located in warm, sunny climates.

A product- and project-site-specific assessment of the effect aggressive conditions may have on the long-term strength of the geosynthetic reinforcement should be considered if the wall environmental conditions are considered to be aggressive.

also be considered if there is potential for seepage of groundwater from the native surrounding soils to the mechanically stabilized backfill. If this is the case, the surrounding soils shall also meet the chemical criteria required for the backfill material if the environment is to be considered nonaggressive, or adequate long-term drainage around the geosynthetic reinforced mass shall be provided to ensure that chemically aggressive liquid does not enter into the reinforced backfill.

Polymer Requirements: Polymers which are likely to have good resistance to long-term chemical degradation shall be used to minimize the risk of the occurrence of significant long-term degradation. The polymer material requirements provided in Table 11.10.6.4.2b-1 shall be met to ensure good resistance to long-term chemical degradation. In this case, the use of a default chemical durability reduction factor, RF_D , of 1.3 as specified in AASHTO R 69 is acceptable, provided the wall backfill environment is determined to be nonaggressive.

If the wall backfill environment is determined to be aggressive as defined in this Article, or if the geosynthetic reinforcement polymer does not meet the requirements in Table 11.10.6.4.2b-1, then product-specific durability studies shall be carried out prior to product use to determine the product-specific long-term strength reduction factor, RF . These product-specific studies shall be used to estimate the short-term and long-term effects of the aggressive environmental factors on the strength and deformational characteristics of the geosynthetic reinforcement throughout the reinforcement design life as well as the effect of using a geosynthetic reinforcement polymer that does not meet the requirements of Table 11.10.6.4.2b-1.

The use of a default value of 1.3 for RF_D also presumes that the geosynthetic is not excessively damaged during installation, which could expose more of the geosynthetic surface to ions present in the soil that could cause degradation. This is especially important for coated polyester geogrids and geostrips, as there is at least some reliance on the coating to prevent exposure of the underlying polyester fibers to moisture that could cause hydrolysis and degradation of the fibers. Therefore, it may be important to keep the installation damage reduction factor, RF_{ID} , reasonably low (i.e., below 1.7 as specified herein).

More detailed FHWA guidance (Berg et al., 2009) on RF_D indicates that RF_D for polyester (PET) geogrids, based on the same research results as the default reduction factor of 1.3 for the wider pH range defined to be nonaggressive, can be reduced to 1.15 if the soil backfill pH is between 5 and 8. For high density polyethylene (HDPE) geogrids, RF_D can be as low as 1.1 based on long-term experience. The PET geogrid RF_D values provided above are also applicable to coated PET geostrip reinforcement. This more detailed guidance provided in the FHWA manual regarding default values for RF_D is acceptable to use provided that the environmental requirements specified in that manual are met.

Guidelines for product-specific studies to determine RF are provided in Elias et al. (2009) and AASHTO R 69, which is based on WSDOT Standard Practice T925 (WSDOT, 2009). Independent product-specific data from which RF may be determined can be obtained from the AASHTO Product Evaluation & Audit Solutions website.

In Table 11.10.6.4.2b-1, for PET products that do not meet a minimum of 50 percent strength retained after 500 hours in the weatherometer (ASTM D4355), such products may still be used if the maximum time of exposure to sunlight is reduced further than specified in the table with owner approval to do so.

The requirements provided in Table 11.10.6.4.2b-1 utilize available index tests and are consistent with AASHTO R 69. These index tests can provide an approximate measure of relative resistance to long-term chemical degradation of geosynthetics. Values selected as minimum criteria to allow use without additional long-term testing are based on values for such properties determined from long-term research reported in the literature. These values are considered indicative of good long-term performance or represent a readily available current standard within the industry that signifies that a product has been enhanced for long-term environmental exposure.

There is little long-term history or even laboratory data regarding the durability of geosynthetics containing a significant percentage of recycled material. Therefore, their potential long-term performance is unknown, and long-term data should be obtained for products with significant recycled material to verify their performance before using them.

The recommended protocol for estimation of the reduction factors for long-term strength loss primarily apply to polypropylene (PP), high density polyethylene (HDPE), and PET, including other polymers used as coatings for PET geogrids and geostrips (e.g., polyvinyl chloride, designated as PVC, or polyethylene). There are other polymers that are sometimes used for the base polymer in geosynthetic reinforcement. The protocols for installation damage and creep are generally applicable to most polymers used in geosynthetic reinforcement. However, the chemical durability index test procedures and criteria provided in Table 11.10.6.4.2b-1, as well as the default RF_D value of 1.3, may not be applicable to these other polymers. In such cases, long-term durability procedures and criteria may need to be developed through long-term testing programs. Therefore, it is important to know the applicability of the available testing protocols and criteria used to determine an appropriate value of RF_D for the geosynthetic reinforcement polymer. In such cases, a detailed evaluation of the geosynthetic reinforcement by organizations such as the AASHTO Product Evaluation & Audit Solutions program is highly recommended.

Table 11.10.6.4.2b-1—Minimum Requirements for Geosynthetic Products to Allow Use of Default Reduction Factor for Long-Term Degradation

Polymer Type	Property	Test Method	Criteria to Allow Use of Default RF
PP and HDPE	UV Oxidation Resistance	ASTM D4355	Minimum 70% strength retained after 500 hrs. in weatherometer
PET	UV Oxidation Resistance	ASTM D4355	Minimum 50% strength retained after 500 hrs. in weatherometer if geosynthetic will be buried within 1 week, or 70% strength retained if left exposed for more than 1 week
PP	Thermo-Oxidation Resistance	ENV ISO 13438: 2004, Method A	Minimum 50% strength retained after 28 days
Polyethylene	Thermo-Oxidation Resistance	ENV ISO 13438: 2004, Method B	Minimum 50% strength retained after 56 days
PET	Hydrolysis Resistance	Intrinsic Viscosity Method (ASTM D4603) and GRI Test Method GG8, or Determine Directly Using Gel Permeation Chromatography	Minimum Number Average Molecular Weight of 25000
PET	Hydrolysis Resistance	ASTM D7409	Maximum of Carboxyl End Group Content of 30
All Polymers	% Post-Consumer Recycled Material by Weight	Certification of Materials Used	Maximum of 0%

11.10.6.4.3—Design Tensile Resistance**11.10.6.4.3a—Steel Reinforcements**

The nominal reinforcement tensile resistance is determined by multiplying the yield stress by the cross-sectional area of the steel reinforcement after corrosion losses (see Figure 11.10.6.4.1-1). The loss in steel cross-sectional area due to corrosion shall be determined in accordance with Article 11.10.6.4.2a. The reinforcement tensile resistance shall be determined as:

$$T_{at} = \frac{A_c F_y}{b} \quad (11.10.6.4.3a-1)$$

where:

- T_{at} = nominal long-term reinforcement design strength (kips/ft)
 F_y = minimum yield strength of steel (ksi)
 A_c = area of reinforcement, corrected for corrosion loss (Figure 11.10.6.4.1-1) (in.²)
 b = unit width of reinforcement (Figure 11.10.6.4.1-1) (ft)

11.10.6.4.3b—Geosynthetic Reinforcements

The nominal long-term reinforcement tensile strength shall be determined as:

$$T_{at} = \frac{T_{ult}}{RF} \quad (11.10.6.4.3b-1)$$

where:

$$RF = RF_{ID} \times RF_{CR} \times RF_D \quad (11.10.6.4.3b-2)$$

and:

T_{at}	=	nominal long-term reinforcement design strength (kips/ft)
T_{ult}	=	minimum average roll value (MARV) ultimate tensile strength (kips/ft)
RF	=	combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical aging (dim.)
RF_{ID}	=	strength reduction factor to account for installation damage to reinforcement (dim.)
RF_{CR}	=	strength reduction factor to prevent long-term creep rupture of reinforcement (dim.)
RF_D	=	strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (dim.)

Values for RF_{ID} , RF_{CR} , and RF_D shall be determined from product-specific test results as specified in Article 11.10.6.4.2b. Even with product-specific test results, RF_{ID} shall not be less than 1.05, and RF_D shall not be less than 1.1.

11.10.6.4.4—Reinforcement/Facing Connection Design Strength

11.10.6.4.4a—Steel Reinforcements

Connections shall be designed to resist reinforcement load at the connection, T_o , as calculated in accordance with Articles 11.10.6.4.1 and 11.10.10, as well as from differential movements between the reinforced backfill and the wall facing elements.

Elements of the connection which are embedded in the facing element shall be designed with adequate bond length and bearing area in the concrete to resist the connection forces. The capacity of the embedded connector shall be checked by tests as required in Article 5.10.8.3. Connections between steel reinforcement and the wall facing units, e.g., welds, bolts, pins, etc., shall be designed in accordance with Article 6.13.3.

Connection materials shall be designed to accommodate losses due to corrosion in accordance with Article 11.10.6.4.2a. Potential differences between the environment at the face relative to the environment within

C11.10.6.4.3b

T_{at} is the long-term tensile strength required to prevent rupture calculated on a load per unit of reinforcement width basis. T_{ult} is the ultimate tensile strength of the reinforcement determined from wide-width tensile tests specified in ASTM D4595 for geotextiles and ASTM D6637 for geogrids. The value selected for T_{ult} is the MARV for the product to account for statistical variance in the material strength.

RF_{ID} , RF_{CR} , and RF_D are not safety factors, but deterministically reflect the best estimate of actual long-term strength losses that may occur during the specified design life of the geosynthetic. The resistance factor for reinforcement rupture provided in Table 11.5.7-1 is combined with the use of the MARV of T_{ult} to account for the uncertainties in the determination of T_{at} .

C11.10.6.4.4a

For example, temperature variations may be higher near the face than back in the backfill. Moisture content may also be higher near the back of the wall face than in the wall backfill in general.

the reinforced soil mass shall be considered when assessing potential corrosion losses.

11.10.6.4.4b—Geosynthetic Reinforcements

For connections cast into concrete facing panels, the portion of the connection embedded in the concrete facing shall be designed in accordance with Article 5.10.8.3.

For geosynthetic reinforcement connections that are just behind the facing, or for connections in which the geosynthetic is placed between the facing blocks, the nominal long-term geosynthetic connection strength, T_{ac} , on a load per unit reinforcement width basis shall be determined as follows:

$$T_{ac} = \frac{T_{ult} \times CR_{cr}}{RF_D} \quad (11.10.6.4.4b-1)$$

where:

- T_{ac} = nominal long-term reinforcement/facing connection strength per unit of reinforcement width (kips/ft)
- T_{ult} = MARV ultimate tensile strength of soil reinforcement (kips/ft)
- CR_{cr} = long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.)
- RF_D = reduction factor to prevent rupture of reinforcement due to chemical and biological degradation (Article 11.10.6.4.3b) (dim.)

If the geosynthetic reinforcement is placed between facing blocks, T_{ac} shall be determined as a function of vertical confining pressure between the facing blocks. Connection tests shall be conducted in accordance with ASTM D6638 to obtain the short-term connection strength, $T_{ultconn}$.

CR_{cr} shall be determined using RF_{CR} to reduce the short-term (i.e., ultimate) connection strength, $T_{ultconn}$, to account for creep of the geosynthetic at the connection, or shall be based on long-term connection creep tests. If connection creep tests are not conducted, CR_{cr} shall be based on short-term connection tests and shall be determined as follows:

$$CR_{cr} = \frac{T_{ultconn}}{(RF_{CR} T_{lot})} \quad (11.10.6.4.4b-2)$$

where:

- $T_{ultconn}$ = nominal short-term connection strength (lbs/ft)
- RF_{CR} = strength reduction factor to prevent long-term creep rupture of reinforcement (dim.)

C11.10.6.4.4b

The connection test is similar in nature to a wide-width tensile test (ASTM D4595 or ASTM D6637), except that one end of the reinforcement material is sandwiched between two courses of concrete blocks to form one of the grips. This results in the strength of the geosynthetic at the connection being reduced relative to the ultimate wide-width tensile strength. The short-term connection test (ASTM D6638 for segmental concrete block connections) is used to determine the ultimate connection strength, $T_{ultconn}$.

For reinforcements connected to the facing through embedment between facing elements, e.g., segmental concrete block faced walls, the capacity of the connection is conceptually governed by one of two failure modes: rupture, or pullout of the reinforcement. This is consistent with the evaluation of internal wall stability in the reinforced backfill zone, where both the rupture and pullout mode of failure must be considered.

The objective of the connection design is to assess the long-term capacity of the connection. If rupture is the mode of failure, the long-term effects of creep and durability on the geosynthetic reinforcement at the connection, as well as on the connector materials, must be taken into account, as the capacity of the connection is controlled by the reinforcement or connector long-term strength. If pullout is the mode of failure, the capacity of the connection is controlled by the frictional interface between the facing blocks and the geosynthetic reinforcement. It is assumed for design that this interface is not significantly affected by time-dependent mechanisms such as creep or chemical degradation, assuming the pullout resistance available is controlling the connection design.

The load-bearing fibers or ribs of the geosynthetic do not necessarily have to experience rupture in the connection test for the mode of failure to be rupture. If the connector is a material that is susceptible to creep, failure of the connectors between blocks due to creep rupture of the connector could result in long-term connection strength losses. In these cases, the value of CR_{cr} and RF_D to be used in Eq. 11.10.6.4.4b-1 should be based on the durability of the connector, not the geosynthetic.

For additional information on the determination of the long-term creep reduced geosynthetic strength at the connection with the wall facing, see the long-term connection strength protocol as described in Appendix B of Berg et al. (2009) and Bathurst and Huang (2010). To determine T_{cr} , the connection creep testing and evaluation protocol in Berg et al. (2009), which consists of a series of connection creep tests carried out over an extended period of time to evaluate the potential for creep rupture at the connection, should be used. CR_{cr} is taken as the creep-

T_{lot} = ultimate wide-width tensile strength (ASTM D4595 or ASTM D6637) of the geosynthetic material used in the connection tests (lbs/ft)

If CR_{cr} is determined based on long-term connection creep tests, CR_{cr} shall be determined as follows:

$$CR_{cr} = \frac{T_{cre}}{T_{lot}} \quad (11.10.6.4b-3)$$

where:

T_{cre} = long-term creep reduced connection strength for the specified design life (lbs/ft)

T_{lot} = ultimate wide-width tensile strength (ASTM D4595 or ASTM D6637) of the geosynthetic material used in the connection tests (lbs/ft)

Values for RF_{CR} and RF_D shall be determined as specified in Article 11.10.6.4.2b. The environment at the wall face connection may be different than the environment away from the wall face in the wall backfill. This shall be considered when determining RF_{CR} and RF_D .

CR_{cr} shall be determined at the anticipated vertical confining pressure at the wall face between the facing blocks. The vertical confining pressure shall be calculated using the Hinge Height Method as shown in Figure 11.10.6.4.4b-1 for a face batter, ω , of greater than 8 degrees. T_{ac} should not be greater than T_{at} .

Geosynthetic walls may be designed using a flexible reinforcement sheet as the facing using only an overlap with the main soil reinforcement. The overlaps shall be designed using a pullout methodology. By replacing T_{max} with T_o , Eq. 11.10.6.3.2-1 may be used to determine the minimum overlap length required, but in no case shall the overlap length be less than 3.0 ft. If $\tan \rho$ is determined experimentally based on soil to reinforcement contact, $\tan \rho$ shall be reduced by 30 percent where reinforcement-to-reinforcement contact is anticipated.

reduced connection strength, T_{cre} , extrapolated to the specified design life, divided by the ultimate wide-width tensile strength (ASTM D4595 or ASTM D6637) for the reinforcement material lot used for the connection strength testing, T_{lot} .

If the connectors between blocks are intended to be used for maintaining block alignment during wall construction and are not intended for long-term connection shear capacity, the alignment connectors should be removed before assessing the connection capacity for the selected block-geosynthetic combination. If the pins or other connection devices are to be relied upon for long-term capacity, the durability of the connector material must be established.

Requirements for determining RF_{CR} and RF_D from product-specific data are provided in Article 11.10.6.4.3b and its commentary. The use of default reduction factors may be acceptable where the reinforcement load is maximum, i.e., in the middle of the wall backfill, and still not be acceptable at the facing connection if the facing environment is defined as aggressive.

Hinge Height, H_h . The full weight of all segmental facing block units within H_h will be considered to act at the base of the lowermost segmental facing block.

Figure 11.10.6.4.4b-1—Determination of Hinge Height for Segmental Concrete Block Faced MSE Walls

The hinge height, H_h , shown in Figure 11.10.6.4.4b-1, shall be determined as:

$$H_h = 2 \left[(W_u - G_u - 0.5H_u \tan i_b) \cos i_b \right] / \tan(\omega + i_b) \quad (11.10.6.4.4b-2)$$

where:

- H_u = segmental facing block unit height (ft)
- W_u = segmental facing block unit weight, front to back (ft)
- G_u = distance to the center of gravity of a horizontal segmental facing block unit, including aggregate fill, measured from the front of the unit (ft)
- ω = wall batter due to setback per course (degrees)
- H = total height of wall (ft)
- H_h = hinge height (ft)
- i_b = slope of facing base downward into backfill (degrees)

11.10.7—Seismic Design of MSE Walls

11.10.7.1—External Stability

External stability evaluation of MSE walls for seismic loading conditions shall be conducted as specified in Article 11.6.5, except as modified in this Article for MSE wall design.

Wall mass inertial forces, P_{IR} , shall be calculated based on an effective mass having a minimum width equal to the structural facing width, W_u , plus a portion of

C11.10.7.1

Since the reinforced soil mass is not really a rigid block, the inertial forces generated by seismic shaking are unlikely to peak at the same time in different portions of the reinforced mass when reinforcing strips or layers start becoming very long, as in the case of MSE walls with steep backslopes in moderately- to highly-seismic areas. This introduces excessive conservatism if the full length

the reinforced backfill equal to 50 percent of the effective height of the wall. For walls in which the wall backfill surface is horizontal, the effective height shall be taken equal to H in Figure 11.10.7.1-1. For walls with sloping backfills, the inertial force, P_{IR} , shall be based on an effective mass having a height H_2 and a base width equal to a minimum of $0.5 H_2$, in which H_2 is determined as follows:

of the reinforcing strips is used in the inertia determination. Past design practice, as represented in previous editions of these Specifications prior to the 6th, recommended that wall mass inertial force be limited to a soil volume equal to 50 percent of the effective height of the wall.

$$H_2 = H + \frac{0.5H \tan(\beta)}{[1 - 0.5 \tan(\beta)]} \quad (11.10.7.1-1)$$

where:

$$\beta = \text{slope of backfill (degrees)}$$

P_{IR} for sloping backfills shall be determined as:

$$P_{IR} = P_{ir} + P_{is} \quad (11.10.7.1-2)$$

where:

P_{ir} = the inertial force caused by acceleration of the reinforced backfill (kips/ft)

P_{is} = the inertial force caused by acceleration of the sloping soil surcharge above the reinforced backfill (kips/ft)

P_{IR} shall act at the combined centroid of reinforced wall mass inertial force, P_{ir} , and the inertial force resulting from the mass of the soil surcharge above the reinforced wall volume, P_{is} . P_{ir} shall include the inertial force from the wall facing. The determination of the MSE wall inertial forces shall be as illustrated in Figure 11.10.7.1-1.

Figure 11.10.7.1-1—Seismic External Stability of an MSE Wall

11.10.7.2—Internal Stability

Reinforcements shall be designed to withstand horizontal forces generated by the internal inertia force, P_i , and the static forces. The total inertia force, P_i , per unit length of structure shall be considered equal to the mass of the active zone times the wall acceleration coefficient, k_h , reduced for lateral displacement of the wall during shaking. The reduced acceleration coefficient, k_h , should be consistent with the value of k_h used for external stability.

For walls with inextensible (e.g., steel) reinforcement, this inertia force shall be distributed to the reinforcements proportionally to their resistant areas on a load per unit width of wall basis as follows:

$$T_{mi} = P_i \frac{L_{ei}}{\sum_{i=1}^m (L_{ei})} \quad (11.10.7.2-1)$$

C11.10.7.2

In past design practice, as presented in previous editions of these Specifications prior to the 6th, the design method for seismic internal stability assumed that the internal inertial forces generating additional tensile loads in the reinforcement act on an active pressure zone that is assumed to be the same as that for the static loading case. A bilinear zone is defined for inextensible reinforcements such as metallic strips and a linear zone for extensible strips.

Whereas it could reasonably be anticipated that these active zones would extend outwards for seismic cases, as for M-O analyses, results from numerical and centrifuge models indicate that the reinforcement restricts such outward movements and only relatively small changes in location are seen.

In past design practice, as presented in previous editions of these Specifications prior to the 6th, the total inertia force was distributed to the reinforcements in proportion to the effective resistant lengths, L_{ei} . This

For walls with extensible reinforcement, this inertial force shall be distributed uniformly to the reinforcements on a load per unit width of wall basis as follows:

$$T_{md} = \left(\frac{P_i}{n} \right) \quad (11.10.7.2-2)$$

where:

- T_{md} = incremental dynamic inertia force at Layer i (kips/ft)
- P_i = internal inertia force due to the weight of backfill within the active zone, i.e., the shaded area on Figure 11.10.7.2-1 (kips/ft)
- $K_h W_a$ = where W_a is the weight of the active zone and K_h is calculated as specified in Article 11.6.5.1.
- n = total number of reinforcement layers in the wall (dim)
- L_{ei} = effective reinforcement length for layer i (ft)

This pressure distribution should be determined from the total inertial force using k_h (after reduction for wave scattering and lateral displacement).

The total factored load applied to the reinforcement on a load per unit of wall width basis as shown in Figure 11.10.7.2-1 is determined as follows:

$$T_{totalf} = \gamma_{seis} (T_{max} + T_{md}) \quad (11.10.7.2-3)$$

where:

- T_{max} = the static load applied to the reinforcements determined as specified in Article 11.10.6.2.1 (kips/ft)
- γ_{seis} = the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load for Extreme Event I (dim)

The value for γ_{seis} is as specified in Table 3.4.1-1 for EQ in Extreme Event I.

approach followed the finite element modeling conducted by Segrestin and Bastick (1988) and led to higher tensile forces in lower reinforcement layers.

In the case of internal stability evaluation, Vrymoed (1989) used a tributary area approach that assumes that the inertial load carried by each reinforcement layer increases linearly with height above the toe of the wall for equally spaced reinforcement layers. A similar approach was used by Ling et al. (1997) in limit equilibrium analyses as applied to extensible geosynthetic reinforced walls. This concept would suggest that longer reinforcement lengths could be needed at the top of walls with increasing acceleration levels, and the AASHTO approach could be unconservative, at least for geosynthetic reinforced walls. Numerical modeling of both steel and geosynthetic reinforced walls by Bathurst and Hatami (1999) shows that the distribution of the reinforcement load increase caused by seismic loading tends to become more uniform with depth as the reinforcement stiffness decreases, resulting in a uniform distribution for geosynthetic reinforced wall systems and a triangular distribution for typical steel reinforced wall systems. Hence, the Segrestin and Bastick (1988) method has been preserved for steel reinforced wall systems and, for geosynthetic reinforced wall systems, a uniform load distribution approach is specified.

With regard to the horizontal acceleration coefficient, k_h , past editions of these Specifications prior to the 6th have not allowed k_h to be reduced to account for lateral deformation. Based on the excellent performance of MSE walls in earthquakes to date, it appears that this is likely a conservative assumption and it is therefore reasonable to allow reduction of k_h for internal stability design corresponding to the lateral displacement permitted in the design of the wall for external stability.

The load factor for reinforcement load due to dead load, T_{max} , and the seismically induced load, T_{md} , is not given a specific designations in Table 3.4.1-1, but instead are set equal to 1.0 under the load designation EQ. The designation for this load factor of γ_{seis} is provided in Eqs. 11.10.7.2-3 through 11.10.7.2-5 to demonstrate that T_{totalf} is indeed a factored load.

S_{rt}	=	ultimate reinforcement tensile resistance required to resist dynamic load component (kips/ft)
R_c	=	reinforcement coverage ratio, specified in Article 11.10.6.4.1 (dim.)
RF	=	combined strength reduction factor to account for potential long-term degradation due to installation damage, creep, and chemical aging, specified in Article 11.10.6.4.3b (dim.)
RF_{ID}	=	strength reduction factor to account for installation damage to reinforcement, specified in Article 11.10.6.4.3b (dim.)
RF_D	=	strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation, specified in Article 11.10.6.4.3b (dim.)

The required ultimate tensile resistance of the geosynthetic reinforcement shall be determined as:

$$T_{ult} = S_{rs} + S_{rt} \quad (11.10.7.2-6)$$

For pullout of steel or geosynthetic reinforcement:

$$L_e \geq \frac{T_{totalf}}{\left(\phi (0.8F^* \alpha \sigma_v C R_c) \right)} \quad (11.10.7.2-7)$$

where:

L_e	=	length of reinforcement in resisting zone (ft)
T_{total}	=	maximum factored reinforcement tension from Eq. 11.10.7.2-2 (kips/ft)
ϕ	=	resistance factor for reinforcement pullout from Table 11.5.7-1 (dim.)
F^*	=	pullout friction factor (dim.)
α	=	scale effect correction factor (dim.)
σ_v	=	unfactored vertical stress at the reinforcement level in the resistant zone (ksf)
C	=	overall reinforcement surface area geometry factor (dim.)
R_c	=	reinforcement coverage ratio, specified in Article 11.10.6.4.1 (dim.)

For seismic loading conditions, the value of F^* , the pullout resistance factor, is reduced to 80 percent of the value used for static design, unless dynamic pullout tests are performed to directly determine the F^* value. Hence, the coefficient of 0.8 is included in Eq. 11.10.7.2-7.

11.10.7.3—Facing Reinforcement Connections

C11.10.7.3

Facing elements shall be designed to resist the seismic loads determined as specified in Article 11.10.7.2, i.e., T_{total} . Facing elements shall be designed in accordance with applicable provisions of Sections 5, 6, and 8 for reinforced concrete, steel, and timber, respectively, except that for the Extreme Event I limit state, all resistance factors should be 1.0, unless otherwise specified for this limit state.

For segmental concrete block faced walls, the blocks located above the uppermost backfill reinforcement layer

shall be designed to resist toppling failure during seismic loading.

For geosynthetic connections subjected to seismic loading, the factored long-term connection strength, ϕT_{ac} , must be greater than the factored reinforcement load, T_{totalf} . If the connection strength is partially or fully dependent on friction between the facing blocks and the reinforcement, the connection strength to resist seismic loads shall be reduced to 80 percent of its static value as follows:

For the static component of the load:

$$S_{rs} \geq \frac{\gamma_{seis} T_{max} RF_D}{0.8 \phi CR_{cr} R_c} \quad (11.10.7.3-1)$$

For the dynamic component of the load:

$$S_{rt} \geq \frac{\gamma_{seis} T_{md} RF_D}{0.8 \phi CR_u R_c} \quad (11.10.7.3-2)$$

where:

- γ_{seis} = the Extreme Event I load factor for reinforcement load due to dead load plus seismically induced reinforcement load (dim.)
- S_{rs} = ultimate reinforcement tensile resistance required to resist static load component (kip/ft)
- T_{max} = applied load to reinforcement (kip/ft)
- RF_D = reduction factor to prevent rupture of reinforcement due to chemical and biological degradation specified in Article 11.10.6.4.4b (dim.)
- ϕ = resistance factor from Table 11.5.7-1 (dim.)
- CR_{cr} = long-term connection strength reduction factor to account for reduced ultimate strength resulting from connection (dim.)
- R_c = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)
- S_{rt} = ultimate reinforcement tensile resistance required to resist dynamic load component (kip/ft)
- T_{md} = factored incremental dynamic inertia force (kip/ft)
- CR_u = short-term reduction factor to account for reduced ultimate strength resulting from connection as specified in Article C11.10.6.4.4b (dim.)

For structural connections that do not rely on a frictional component, the 0.8 multiplier may be removed from Eqs. 11.10.7.3-1 and 11.10.7.3-2.

The required ultimate tensile resistance of the geosynthetic reinforcement at the connection is:

$$T_{ult} = S_{rs} + S_{rf} \quad (11.10.7.3-3)$$

For structures in Seismic Performance Zones 3 or 4, facing connections in segmental block faced walls shall use shear resisting devices between the facing blocks and soil reinforcement, such as shear keys, pins, etc., and shall not be fully dependent on frictional resistance between the soil reinforcement and facing blocks.

The connection capacity of a facing/reinforcement connection system that is fully dependent on the shear resisting devices for the connection capacity will not be significantly influenced by the normal stress between facing blocks. The percentage of connection load carried by the shear resisting devices relative to the frictional resistance to meet the specification requirements should be determined based on past successful performance of the connection system.

Some judgment may be required to determine whether or not a specific shear resisting device or combination of devices is sufficient to meet this requirement in Seismic Performance Zones 3 and 4. The ability of the shear resisting device or devices to keep the soil reinforcement connected to the facing, should vertical acceleration significantly reduce the normal force between the reinforcement and the facing blocks, should be evaluated. Note that in some cases, coarse angular gravel placed within the hollow core of the facing blocks, provided that the gravel can remain interlocked during shaking, can function as a shear restraining device to meet the requirements of this Article.

11.10.7.4—Wall Details for Improved Seismic Performance

The details specified in Article 11.6.5.6 for gravity walls should also be addressed for MSE walls in seismically active areas, defined as Seismic Zone 2 or higher. The following additional requirements should also be addressed for MSE walls:

- *Second Stage Fascia Panels:* The connections used to connect the fascia panels to the main gravity wall structure should be designed to minimize movement between panels during shaking.
- *Soil Reinforcement Length:* A minimum soil reinforcement length of $0.7H$ should be used. A greater soil reinforcement length in the upper 2.0 to 4.0 ft of wall height (a minimum of two reinforcement layers) should also be considered to improve the seismic performance of the wall. If the wall is placed immediately in front of a very steep slope, existing shoring, or permanent wall, the reinforcement within the upper 2.0 to 4.0 ft of wall height (a minimum of two reinforcement layers, applicable to wall heights of 10.0 ft or more) should be extended to at least 5.0 ft behind the steep slope or existing wall.

C11.10.7.4

These recommended details are based on previous experiences with walls in earthquakes (e.g., see Yen et al., 2011). Walls that did not address these details tended to have a higher frequency of problems than walls that did consider these details.

With regard to preventing joints from opening up during shaking, such as at corners and protrusions through the wall face, Article C11.6.5.6 applies. For panel-faced MSE walls placed against a cast-in-place concrete curtain wall or similar structure, a 4.0-in. lip on the cast-in-place structure to cover the joint with the MSE wall facing has been used successfully.

Historically, corners and abrupt alignment changes in walls (e.g., corners and short-radius turns at an enclosed angle of 120 degrees or less) have had a higher incidence of performance problems during earthquakes than relatively straight sections of the wall alignment, as the corners may become damaged and separate. This should be considered when designing and detailing a wall corner for seismic loading. Reinforcement layers should be placed in both directions at the corner, abrupt alignment change, or short-radius turn. In addition, the special corner facing element, used to bridge across a continuous vertical corner joint, should also have a reinforcement layers attached to it to provide stability for the corner panel element. For modular block faced walls in which the blocks are staggered such that a continuous vertical joint is not formed, placing soil reinforcement as continuous or staggered layers across the corner is an

acceptable approach to provide an adequate degree of continuity and stability across the corner. For concrete panel faced systems, that portion of the corner or abrupt wall facing alignment change where the soil reinforcement cannot achieve its full length required to meet internal stability requirements, the end of the reinforcement layer should be structurally tied to the back of the adjacent panel. The reinforcement layers that are tied to both sides of the corner should be designed considering the corner as a bin structure. Careful attention should be undertaken in the placement and compaction of the fill near wall corners since the more difficult access can cause the fill not to be compacted to its optimum density, potentially causing increased deformations at the corners during a seismic event.

Note that the corner or abrupt alignment change enclosed angle as defined in the previous paragraph can either be internal or external to the wall.

With regard to wall backfill materials, the provisions of Article 11.6.5.6 shall apply.

When structures and foundations within the active zone of the reinforced wall backfill are present, significant wall movements and damage have occurred during earthquakes due to inadequate reinforcement length behind the facing due to the presence of a foundation, drainage structure, or other similar structure. The details provided in Article 11.10.10.4 are especially important to implement for walls subjected to seismic loading.

Past experience with second stage precast incremental facing panels indicates that performance problems can occur if the connections between the panels and the first stage wall can rotate or otherwise have some looseness, especially if wall settlement is not complete. Therefore, incremental second stage facia panels should be avoided for walls located in seismically active areas (as defined in Article 11.5.4.2 for sites requiring seismic analysis). Full height second stage precast or cast-in-place concrete panels have performed more consistently, provided the panels are installed after wall settlement is essentially complete.

A minimum soil reinforcement length of $0.7H$ has been shown to consistently provide good performance of MSE walls in earthquakes. Extending the upper two layers of soil reinforcement a few feet behind the $0.7H$ reinforcement length has, in general, resulted in modest improvement in the wall deformation in response to seismic loading, especially if higher silt content backfill must be used. If MSE walls are placed in front of structures or hard soil or rock steep slopes that could have different deformation characteristics than the MSE wall reinforced backfill, there is a tendency for a crack to develop at the vertical or near-vertical boundary of the two materials. Soil reinforcements that extend an adequate distance behind the boundary have been shown to prevent such a crack from developing. It is especially important to extend the length of the upper reinforcement layers if there is inadequate room to have a reinforcement length of $0.7H$ in the bottom portion of the wall, provided

11.10.8—Drainage

Internal drainage measures shall be provided for all structures to prevent saturation of the reinforced backfill and to intercept any surface flows containing aggressive elements.

MSE walls in cut areas and side-hill fills with established groundwater levels shall be constructed with drainage blankets in back of, and beneath, the reinforced zone.

For MSE walls supporting roadways which are chemically deiced in the winter, an impervious membrane may be required below the pavement and just above the first layer of soil reinforcement to intercept any flows containing deicing chemicals. The membrane shall be sloped to drain away from the facing to an intercepting longitudinal drain outletted beyond the reinforced zone. Typically, a roughened surface PVC, HDPE, or linear low-density polyethylene (LLDPE) geomembrane with a minimum thickness of 30 mils. should be used. All seams in the membrane shall be welded to prevent leakage.

11.10.9—Subsurface Erosion

The provisions of Article 11.6.3.5 shall apply.

11.10.10—Special Loading Conditions

11.10.10.1—Concentrated Dead Loads

The distribution of stresses within and behind the wall resulting from concentrated loads applied to the wall top or behind the wall shall be determined in accordance with Article 3.11.6.3.

Figure 11.10.10.1-1 illustrates the combination of loads using superposition principles to evaluate external and internal wall stability. Depending on the size and location of the concentrated dead load, the location of the boundary between the active and resistant zones may have to be adjusted as shown in Figure 11.10.10.1-2.

For distribution of loads within the reinforced soil zone of the wall, the factored horizontal force carried by the reinforcement at any reinforcement level, T_{total} , shall be determined by superposition as follows:

$$T_{totalf} = \gamma_{p-EV} T_{max} + \gamma_{p-ES} S_v (k_r \Delta \sigma_v + \Delta \sigma_H) \quad (11.10.10.1-1)$$

where:

γ_{p-EV} = load factor for vertical earth pressure, EV , specified in Table 3.4.1-2 (dim.)

γ_{p-ES} = load factor for earth surcharge, ES , in Table 3.4.1-2

the requirements of Article 11.10.2.1 and commentary are met.

For additional information on good wall details for MSE walls, see Berg et al. (2009).

C11.10.8

MSE wall backfill meeting the requirements of Article 7.3.6.3 in the *AASHTO LRFD Bridge Construction Specifications* may not be adequately free draining to prevent build-up of water in the backfill, resulting in unanticipated loading of the reinforcement and facing. The ability of the backfill to drain quickly should be considered when deciding the type of drainage needed. However, in general, water from stormwater runoff as well as ground water that could seep into the backfill should be prevented from entering the MSE wall backfill and from building up immediately behind the MSE wall.

C11.10.10.1

For walls with a facing batter of greater than 10 degrees, see Article C11.10.6.2.1c to determine the lateral earth pressure coefficient.

- $\Delta\sigma_v$ = vertical soil stress due to concentrated load such as a footing load (ksf)
 $\Delta\sigma_H$ = horizontal stress at reinforcement level resulting from a concentrated horizontal surcharge load (ksf)
 S_v = tributary layer vertical thickness for reinforcement (ft)
 k_r = lateral earth pressure coefficient (dim.)

At the connection with the wall facing, Eq. 11.10.10.1-2 shall be modified to be as follows:

$$T_{totalfo} = \gamma_{p-EV} T_o + \gamma_{p-ES} S_v (k_r \Delta\sigma_v + \Delta\sigma_H) \quad (11.10.10.1-2)$$

where:

- $T_{totalfo}$ = the factored reinforcement load at the connection to the facing (kips/ft)
 T_o = nominal (unfactored) tensile load at reinforcement/facing connection (kips/ft)

All other variables are as defined previously.

For the Coherent Gravity Method, k_r shall be determined from Figure 11.10.6.2.1d-1. Additionally for the Coherent Gravity Method, the contribution of the concentrated dead loads to the load eccentricity at each reinforcement layer shall be estimated using the principles illustrated in Figure 11.10.6.2.1d-2. Any external concentrated loads present which contribute to T_{max} shall be factored as specified in Tables 3.4.1-1 and 3.4.1-2.

For the Stiffness Method, k_r in Eq. 11.10.10.1-1 shall be equal to k_{avh} for walls with a facing batter of 10 degrees or less from the vertical, determined as specified in Article 11.10.6.2.1e. Any external concentrated loads added by superposition which contribute to T_{max} shall be factored as specified in Tables 3.4.1-1 and 3.4.1-2.

For typical bridge footing foundation loads, adding the reinforcement load increase due to the footing foundation to T_{max} using superposition can be overly conservative, especially for the Soil Failure Limit State as calculated in Article 11.10.4.3 (i.e., calculated strains are too high). In this case, at least until improvements to the Stiffness Method are developed to address this issue, one of the other internal stability T_{max} calculation methods, such as the Coherent Gravity Method for steel reinforced MSE walls, or the Simplified Method as described in Appendix B11 for steel and geosynthetic reinforced MSE walls, should be used to determine T_{max} for the internal stability design when a footing foundation is supported by the MSE wall.

Notes:

These equations assume that concentrated dead load #2 is located within the active zone behind the reinforced soil mass.

For relatively thick facing elements (e.g., segmental concrete facing blocks), it is acceptable to include the facing dimensions and weight in sliding, overturning, and bearing capacity calculations (i.e., use B in lieu of L).

P_{V1} , P_{H1} , $\Delta\sigma_{v1}$, $\Delta\sigma_{v2}$, $\Delta\sigma_{H2}$, and I_2 are as determined from Figures 3.11.6.3-1 and 3.11.6.3-2, and F_p results from P_{V2} (i.e., $K\Delta\sigma_{v2}$ from Figure 3.11.6.3-1. H is the total wall height at the face. h_p is the distance between the centroid of the trapezoidal distribution shown and the bottom of that distribution.

Figure 11.10.10.1-1—Superposition of Concentrated Dead Loads for External and Internal Stability Evaluation

Figure 11.10.10.1-2—Location of Maximum Tensile Force Line in Case of Large Surcharge Slabs (Inextensible Reinforcements)

11.10.10.2—Traffic Loads and Barriers

Traffic loads shall be treated as uniform surcharge loads in accordance with the criteria outlined in Article 3.11.6.2. The live load surcharge pressure shall not be less than 2.0 ft of earth. Parapets and traffic barriers, constructed over or in line with the front face of the wall, shall be designed to resist overturning moments by their own mass. Base slabs shall not have any transverse joints, except construction joints, and adjacent slabs shall be joined by shear dowels. The upper layer(s) of soil reinforcements shall have sufficient tensile capacity to resist a concentrated horizontal load of $\gamma_{LL}P_H$ where $P_H = 10$ kips distributed over a barrier length of 5.0 ft. This force distribution accounts for the local peak force in the soil reinforcements in the vicinity of the concentrated load. This distributed force would be equal to $\gamma_{LL}P_{HI}$ where $P_{HI} = 2.0$ kips/ft and is applied as shown in Figure 3.11.6.3-2a. $\gamma_{LL}P_{HI}$ would be distributed to the reinforcements assuming b_f equal to the width of the base slab. Adequate space shall be provided laterally between the back of the facing panels and the traffic barrier/slab to allow the traffic barrier and slab to resist the impact load in sliding and overturning without directly transmitting load to the top facing units.

For checking pullout safety of the reinforcements, the lateral traffic impact load shall be distributed to the upper soil reinforcement using Figure 3.11.6.3-2a, assuming b_f equal to the width of the base slab. The full length of reinforcements shall be considered effective in resisting pullout due to the impact load. The upper layer(s) of soil reinforcement shall have sufficient pullout capacity to resist a horizontal load of $\gamma_{LL}P_{HI}$ where $P_{HI} = 10.0$ kips distributed over a 20.0 ft base slab length.

Due to the transient nature of traffic barrier impact loads, when designing for reinforcement rupture, the geosynthetic reinforcement must be designed to resist the static and transient (impact) components of the load as follows:

For the static component, see Eq. 11.10.7.2-4.

For the transient components:

$$\gamma_{CT}\Delta\sigma_H S_v \leq \frac{\phi S_{rt} R_c}{RF_D RF_D} \quad (11.10.10.2-1)$$

where:

- γ_{CT} = load factor for vehicular impact loads (dim.)
- $\Delta\sigma_H$ = traffic barrier impact stress applied over reinforcement tributary area per Article 11.10.10.1 (ksf)
- S_v = vertical spacing of reinforcement (ft)
- S_{rt} = ultimate reinforcement tensile resistance required to resist dynamic load component (kips/ft)

C11.10.10.2

The force distribution for pullout calculations is different than that used for tensile calculations because the entire base slab must move laterally to initiate a pullout failure due to the relatively large deformation required.

Refer to C11.10.7.2 which applies to transient loads, such as impact loads on traffic barriers, as well as earthquake loads.

- R_c = reinforcement coverage ratio from Article 11.10.6.4.1 (dim.)
- RF_{ID} = strength reduction factor to account for installation damage to reinforcement from Article 11.10.6.4.3b (dim.)
- RF_D = strength reduction factor to prevent rupture of reinforcement due to chemical and biological degradation from Article 11.10.6.4.3b (dim.)

The reinforcement strength required for the static load component must be added to the reinforcement strength required for the transient load component to determine the required total ultimate strength using Eq. 11.10.7.3-3.

Parapets and traffic barriers shall satisfy crash testing requirements as specified in Section 13. The anchoring slab shall be strong enough to resist the ultimate strength of the standard parapet.

Flexible post and beam barriers, when used, shall be placed at a minimum distance of 3.0 ft from the wall face, driven 5.0 ft below grade, and spaced to miss the reinforcements where possible. If the reinforcements cannot be missed, the wall shall be designed accounting for the presence of an obstruction as described in Article 11.10.10.4. The upper two rows of reinforcement shall be designed for an additional horizontal load γP_{H1} , where P_{H1} = 300 lb per linear ft of wall, 50 percent of which is distributed to each layer of reinforcement.

11.10.10.3—Hydrostatic Pressures

For structures along rivers and streams, a minimum differential hydrostatic pressure equal to 3.0 ft of water shall be considered for design. This load shall be applied at the high-water level. Effective unit weights shall be used in the calculations for internal and external stability beginning at levels just below the application of the differential hydrostatic pressure.

C11.10.10.3

Situations where the wall is influenced by tide or river fluctuations may require that the wall be designed for rapid drawdown conditions, which could result in differential hydrostatic pressure considerably greater than 3.0 ft, or alternatively rapidly draining backfill material such as shot rock or open graded coarse gravel can be used as backfill. Backfill material meeting the gradation requirements in the *AASHTO LRFD Bridge Construction Specifications* for MSE structure backfill is not considered to be rapid draining.

The phreatic surface for drawdown calculations will depend on the permeability of the MSE backfill. Using open-graded “free-draining” backfill is preferred for good performance, however its use does not preclude the need to do a drawdown analysis.

11.10.10.4—Obstructions in the Reinforced Soil Zone

If the placement of an obstruction in the wall soil reinforcement zone such as a catch basin, grate inlet, signal or sign foundation, guardrail post, or culvert cannot be avoided, the design of the wall near the obstruction shall be modified using one of the following alternatives:

- 1) Assuming reinforcement layers must be partially or fully severed in the location of the obstruction,

C11.10.10.4

Field cutting of longitudinal or transverse wires of metal grids, e.g., bar mats, should not be allowed unless

design the surrounding reinforcement layers to carry the additional load which would have been carried by the severed reinforcements.

- 2) Place a structural frame around the obstruction capable of carrying the load from the reinforcements in front of the obstruction to reinforcements connected to the structural frame behind the obstruction, as illustrated in Figure 11.10.10.4-1.
- 3) If the soil reinforcements consist of discrete strips and depending on the size and location of the obstruction, it may be possible to splay the reinforcements around the obstruction.

For Alternative 1, the portion of the wall facing in front of the obstruction shall be made stable against a toppling (overturning) or sliding failure. If this cannot be accomplished, the soil reinforcements between the obstruction and the wall face can be structurally connected to the obstruction such that the wall face does not topple, or the facing elements can be structurally connected to adjacent facing elements to prevent this type of failure.

For the second alternative, the frame and connections shall be designed in accordance with Section 6 for steel frames.

For the third alternative, the splay angle, measured from a line perpendicular to the wall face, shall be small enough that the splaying does not generate moment in the reinforcement or the connection of the reinforcement to the wall face. The tensile resistance of the splayed reinforcement shall be reduced by the cosine of the splay angle.

If the obstruction must penetrate through the face of the wall, the wall facing elements shall be designed to fit around the obstruction such that the facing elements are stable, i.e., point loads should be avoided, and such that wall backfill soil cannot spill through the wall face where it joins the obstruction. To this end, a collar next to the wall face around the obstruction may be needed.

If driven piles or drilled shafts must be placed through the reinforced zone, the recommendations provided in Article 11.10.11 shall be followed.

one of the alternatives in Article 11.10.10.4 is followed and compensating adjustment is made in the wall design.

Typically, the splay of reinforcements is limited to a maximum of 15 degrees.

Note that it may be feasible to connect the soil reinforcement directly to the obstruction, depending on the reinforcement type and the nature of the obstruction.

Figure 11.10.10.4-1—Structural Connection of Soil Reinforcement around Backfill Obstructions

11.10.11—MSE Abutments

Abutments with a bridge footing placed on top of the reinforced soil zone of an MSE wall shall be proportioned to meet the criteria specified in Articles 11.6.2 through 11.6.6.

The reinforced soil zone below the abutment footing shall be designed for the additional loads imposed by the footing pressure and supplemental earth pressures resulting from horizontal loads applied at the bridge seat and from the backwall. The footing load may be distributed as described in Article 11.10.10.1.

The factored horizontal force carried by the reinforcement at any reinforcement level, T_{total} , shall be determined by superposition using Eq. 11.10.10.1-1.

The effective length used for calculations of internal stability under the abutment footing shall be as described in Article 11.10.10.1 and Figure 11.10.10.1-2.

The minimum distance from the centerline of the bearing on the abutment to the outer edge of the facing shall be 3.5 ft. The minimum distance between the back face of the panel and the footing shall be 6.0 in.

Where significant frost penetration is anticipated, the abutment footing shall be placed on a bed of compacted coarse aggregate 3.0 ft thick as described in Article 11.10.2.2.

The density, length, and cross-section of the soil reinforcements designed for support of the abutment shall be carried on the wingwalls for a minimum horizontal distance equal to 50 percent of the height of the abutment.

C11.10.11

The term “MSE abutment” is defined to represent the case when the bridge footing is placed directly above the reinforced soil zone of an MSE wall.

For analysis of the spread footing on top of the reinforced soil zone, the following values of bearing resistance of the reinforced soil zone may be used (Berg et al., 2009):

- For service limit state, bearing resistance = 4 ksf to limit the vertical movement to less than approximately 0.5 in. within the reinforced soil mass; and
- For strength limit state, factored bearing resistance = 7 ksf.

The minimum length of reinforcement, based on experience, has been $0.6(H + d) + 6.5$ ft. The length of reinforcement should be constant throughout the height to limit differential settlements across the reinforced zone. Differential settlements could overstress the reinforcements.

The permissible level of differential settlement at abutment structures should preclude damage to superstructure units. This subject is discussed in Article 10.6.2.2. In general, abutments should not be constructed on mechanically stabilized embankments if anticipated differential settlements between abutments or between piers and abutments are greater than one-half the limiting differential settlements described in Article C10.5.2.2.

In pile or drilled shaft supported abutments, the horizontal forces transmitted to the deep foundation elements shall be resisted by the lateral capacity of the deep foundation elements by provision of additional reinforcements to tie the drilled shaft or pile cap into the soil mass, or by batter piles. Lateral loads transmitted from the deep foundation elements to the reinforced backfill may be determined using a p - y lateral load analysis technique. The facing shall be isolated from horizontal loads associated with lateral pile or drilled shaft deflections. A minimum clear distance of 1.5 ft shall be provided between the facing and deep foundation elements. Piles or drilled shafts shall be specified to be placed prior to wall construction and cased through the fill if necessary.

The equilibrium of the system should be checked at each level of reinforcement below the bridge seat.

Due to the relatively high bearing pressures near the panel connections, the adequacy and ultimate capacity of panel connections should be determined by conducting pullout and flexural tests on full-sized panels.

Moments should be taken at each level under consideration about the centerline of the reinforced mass to determine the eccentricity of load at each level. A uniform vertical stress is then calculated using a fictitious width taken as $(B - 2e)$, and the corresponding horizontal stress should be computed by multiplying by the appropriate coefficient of lateral earth pressure.

11.11—PREFABRICATED MODULAR WALLS

11.11.1—General

Prefabricated modular systems may be considered where conventional gravity, cantilever, or counterfort concrete retaining walls are considered.

C11.11.1

Prefabricated modular wall systems, whose elements may be proprietary, generally employ interlocking soil-filled reinforced concrete or steel modules or bins, rock-filled gabion baskets, precast concrete units, or dry cast segmental masonry concrete units (without soil reinforcement) which resist earth pressures by acting as gravity retaining walls. Prefabricated modular walls may also use their structural elements to mobilize the dead weight of a portion of the wall backfill through soil arching to provide resistance to lateral loads. Typical prefabricated modular walls are shown in Figure C11.11.1-1.

Figure C11.11.1-1—Typical Prefabricated Modular Gravity Walls

Prefabricated modular wall systems shall not be used under the following conditions:

- On curves with a radius of less than 800 ft, unless the curve can be substituted by a series of chords.
- Steel modular systems shall not be used where the groundwater or surface runoff is acid contaminated or where deicing spray is anticipated.

11.11.2—Loading

The provisions of Articles 11.6.1.2 and 3.11.5.9 shall apply, except that shrinkage and temperature effects need not be considered.

11.11.3—Movement at the Service Limit State

The provisions of Article 11.6.2 shall apply as applicable.

C11.11.3

Calculated longitudinal differential settlements along the face of the wall should result in a slope less than $1/200$.

11.11.4—Safety against Soil Failure

11.11.4.1—General

For sliding and overturning stability, the system shall be assumed to act as a rigid body. Determination of stability shall be made at every module level.

Passive pressures shall be neglected in stability computations, unless the base of the wall extends below the total scour depth from the scour check flood, or depth of freeze-thaw, or other disturbance. For these cases only, the embedment below the greater of these depths may be considered effective in providing passive resistance.

11.11.4.2—Sliding

The provisions of Article 10.6.3.4 shall apply.

Computations for sliding stability may consider that the friction between the soil-fill and the foundation soil, and the friction between the bottom modules or footing and the foundation soil are effective in resisting sliding. The coefficient of sliding friction between the soil-fill and foundation soil at the wall base shall be the lesser of the value of ϕ_f of the soil fill and the value of ϕ_f of the foundation soil. The coefficient of sliding friction between the bottom modules or footing and the foundation soil at the wall base shall be reduced, as necessary, to account for any smooth contact areas.

In the absence of specific data, a maximum friction angle of 30 degrees shall be used for ϕ_f for granular soils. Tests should be performed to determine the friction angle of cohesive soils considering both drained and undrained conditions.

11.11.4.3—Bearing Resistance

The provisions of Article 10.6.3 shall apply.

Bearing resistance shall be computed by assuming that dead loads and earth pressure loads are resisted by point supports per unit length at the rear and front of the modules or at the location of the bottom legs. A minimum of 80 percent of the soil weight inside the modules shall be considered to be transferred to the front and rear support points. If foundation conditions require a footing under the total area of the module, all of the soil weight inside the modules shall be considered.

11.11.4.4—Overturning

The provisions of Article 11.6.3.3 shall apply.

A maximum of 80 percent of the soil-fill inside the modules is effective in resisting overturning moments.

C11.11.4.3

Concrete modular systems are relatively rigid and are subject to structural damage due to differential settlements, especially in the longitudinal direction. Therefore, bearing resistance for footing design should be determined as specified in Article 10.6.

C11.11.4.4

The entire volume of soil within the module cannot be counted on to resist overturning, as some soil will not arch within the module. If a structural bottom is provided to retain the soil within the module, no reduction of the soil weight to compute overturning resistance is warranted.

11.11.4.5—Subsurface Erosion

Bin walls may be used in scour-sensitive areas only where their suitability has been established. The provisions of Article 11.6.3.4 shall apply.

11.11.4.6—Overall Stability

The provisions of Article 3.4.1 and Article 11.6.3.7 shall apply.

11.11.4.7—Passive Resistance and Sliding

The provisions of Articles 10.6.3.4 and 11.6.3.6 shall apply, as applicable.

11.11.5—Safety against Structural Failure

11.11.5.1—Module Members

Prefabricated modular units shall be designed for the factored earth pressures behind the wall and for factored pressures developed inside the modules. Rear face surfaces shall be designed for both the factored earth pressures developed inside the modules during construction and the difference between the factored earth pressures behind and inside the modules after construction. Strength and reinforcement requirements for concrete modules shall be in accordance with Section 5.

Strength requirements for steel modules shall be in accordance with Section 6. The net section used for design shall be reduced in accordance with Article 11.10.6.4.2a.

Factored bin pressures shall be the same for each module and shall not be less than:

$$P_b = \gamma \gamma_{p-EV} b \quad (11.11.5.1-1)$$

where:

P_b = factored pressure inside bin module (ksf)

 γ = soil unit weight (kcf)

γ_{p-EV} = load factor for vertical earth pressure, specified in Table 3.4.1-2

$$b = \text{width of bin module (ft)}$$

C11.11.5.1

Structural design of module members is based on the difference between pressures developed inside the modules (bin pressures) and those resulting from the thrust of the backfill. The recommended bin pressure relationships are based on relationships obtained for long trench geometry, and are generally conservative.

Steel reinforcing shall be symmetrical on both faces unless positive identification of each face can be ensured to preclude reversal of units. Corners shall be adequately reinforced.

11.11.6—Seismic Design for Prefabricated Modular Walls

C11.11.6

The provisions of Article 11.6.5 shall apply.

The prefabricated modular wall develops resistance to seismic loads from both the geometry and the weight of the wall section. The primary design issues for seismic loading are global stability, external stability (i.e., sliding, overturning, and bearing), and internal stability. External stability includes the ability of each lift within the wall to also meet external stability requirements. Interlocking between individual structural sections and the soil fill within the wall needs to be considered in this evaluation.

The primary difference for this wall type relative to a gravity or semigravity wall is that sliding and overturning can occur at various heights between the base and top of the wall, as this class of walls typically uses gravity to join sections of the wall together.

The interior of the prefabricated wall elements is normally filled with soil; this provides both additional weight and shear between structural elements. The contributions of the earth, as well as the batter on the wall, need to be considered in the analysis.

Similar to the other external stability checks, the overall (global) stability check needs to consider failure surfaces that pass through the wall section, as well as below the base of the wall. The check on stability at mid-level must consider the contributions of both the soil within the wall and any structural interlocking that occurs for the particular modular wall type.

When checking stability at the mid-level of a wall, the additional shear resistance from interlocking of individual wall components will depend on the specific wall type. Usually, interlocking resistance between wall components is provided by the wall supplier.

For wall corners not cast monolithically, a special facing unit formed to go across the corner should be used to provide continuity and stability across a continuous corner vertical joint. Historically, corners and abrupt alignment changes in walls have had a higher incidence of performance problems during earthquakes than relatively straight sections of the wall alignment, as the corners may become damaged and separate. This should be considered when designing and detailing a wall corner for seismic loading. Careful attention should be undertaken in the placement and compaction of the fill near wall corners since the more difficult access can cause the fill not to be compacted to its optimum density, potentially causing increased deformations at the corners during a seismic event.

11.11.7—Abutments

Abutment seats constructed on modular units shall be designed by considering earth pressures and supplemental horizontal pressures from the abutment seat beam and earth pressures on the backwall. The top module shall be proportioned to be stable under the combined actions of normal and supplementary earth pressures. The minimum width of the top module shall be

6.0 ft. The centerline of bearing shall be located a minimum of 2.0 ft from the outside face of the top precast module. The abutment beam seat shall be supported by, and cast integrally with, the top module.

The front face thickness of the top module shall be designed for bending forces developed by supplemental earth pressures. Abutment beam-seat loadings shall be carried to foundation level and shall be considered in the design of footings.

Differential settlement provisions, specified in Article 11.10.4, shall apply.

11.11.8—Drainage

In cut and side-hill fill areas, prefabricated modular units shall be designed with a continuous subsurface drain placed at, or near, the footing grade and outletted as required. In cut and side-hill fill areas with established or potential groundwater levels above the footing grade, a continuous drainage blanket shall be provided and connected to the longitudinal drain system.

For systems with open front faces, a surface drainage system shall be provided above the top of the wall.

11.12—SOIL NAIL WALLS

11.12.1—General Considerations

Soil nail walls, illustrated in Figure 11.12.1-1, most commonly consist of: (a) a soil nail (i.e., steel bar) that is placed in a pre-drilled hole, then grouted along its entire length in the hole; (b) connectors in the soil nail head; and (c) a structurally-continuous reinforced shotcrete or concrete cover (facing) connecting all nail heads.

The feasibility of using a soil nail wall at a particular location should be based on the suitability of the soil and rock conditions at both the wall face and along the length of the nails. Where fill is to be placed above the soil nail wall, or if the wall supports a combination of cut and fill, the fill placed near the wall face should be limited regarding depth of fill placed below the wall top to no more than down to the first row of nails, and the placement and compaction of the fill shall not damage the nails or facing or otherwise compromise the ability of these elements to resist load.

C11.12.1

Soil nail walls are top-down construction structures that are particularly well suited for ground conditions that require vertical or near-vertical cuts, and may be used for both permanent and temporary support. Favorable ground conditions make soil nailing technically feasible and cost effective, compared with other techniques, when:

- the soil being excavated is able to stand unsupported, 3.0 to 6.0 ft high, vertically or near vertical, for 1 to 2 days;
- all soil nails are above the groundwater table; and
- the long-term integrity of the soil nails can be maintained through corrosion protection.

If the soil nail wall retains fill in the upper part of the wall, provisions to protect against nail and facing damage resulting from backfill and subsoil settlement, or backfill and compaction activities above the anchors, should be included.

Soil nail walls may also be feasible to stabilize marginally unstable existing slopes in which a sufficient length of nails can penetrate behind the failure zone and in which the wall installation process will not exacerbate, temporarily or permanently, the stability problem.

The availability or ability to obtain underground easements and proximity of buried facilities to nail locations should also be considered in assessing feasibility.

Horizontal nail spacing, S_h , is typically the same as vertical nail spacing, S_v , and is typically between 4.0 ft and 6.5 ft, with a maximum influence area of $S_h \times S_v \leq 40.0 \text{ ft}^2$. Soil nail spacing may be modified to accommodate the presence of existing underground structures or utilities behind the wall.

Subsurface conditions that are generally well-suited for soil nail applications include dense to very dense granular soils with apparent cohesion; weathered rock without adverse planes of weakness; stiff to hard fine-grained soils; engineered fill; some residual soils; and some glacial till soils.

Examples of unfavorable soil types and ground conditions include dry, poorly-graded cohesionless soils; granular soils with high groundwater; soils with cobbles and boulders; soft to very soft fine-grained soils; collapsible soils; organic soils; highly-corrosive soils; weathered rock with unfavorable planes of weakness; karstic formations; loess; and expansive soils.

Corrosion protection is provided by grouting, epoxy coating, galvanized coating, and encapsulation, or a combination of these methods (not shown in Figure 11.12.1-1). See Article 11.12.8 and FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015) for corrosion protection design considerations.

Figure 11.12.1-1—Typical Cross-Section of a Soil Nail Wall: (a) Overall Cross-Section, and (b) Nail Head Detail. (Lazarte et al., 2015, after Porterfield et al., 1994)

11.12.2—Loading

The provisions of Article 11.6.1.2 shall apply.

Limit equilibrium analysis methods shall be used to assess wall loading and stability for final design. When additional surcharge loads, such as a structure footing load or live load, are applied to the top of the reinforced zone of the soil nail wall, they are factored as specified in Article 3.4.1 for the Strength I Limit state.

C11.12.2

For soil nail walls, the limit equilibrium slope stability analyses to assess overall stability (external to the nail reinforced section) and to determine nail loads (i.e., T_{maxn} , the maximum soil nail force in each soil nail row determined from the limit equilibrium stability analysis) for internal and compound stability (i.e., nail tensile design, nail pullout, and facing design) are as illustrated in Figure C11.12.2-1. Determination of T_{maxn} for internal and compound stability for nail tensile resistance, pullout, and facing design is done at the strength limit state, and if extreme events such as seismic

are being considered, T_{maxsn} is estimated also considering the additional loads applicable to the extreme event being considered.

Available soil nail wall analysis computer programs analyze soil nail tension and pullout as a single design step to achieve a target minimum level of safety. The tension in the nails, T_{maxsn} , is determined at the target soil failure resistance factor (see Articles 11.5.7 and 11.6.3.7) for the wall (i.e., $1/FS$ output by the computer program, in which FS is typically 1.3 or 1.5). Reduction factors (also termed “safety factors”) are applied to soil nail tensile and pullout resistance to account for variability in the pullout and nail tensile resistance. See Lazarte et al. (2015) for additional guidance on the application of typical soil nail wall design programs to an LRFD framework.

Available computer programs used for soil nail wall stability analysis typically provide values of T_{maxsn} in each soil nail row that correspond to the target level of safety. The T_{maxsn} values obtained may vary depending on the volume of soil between the wall face and the critical surface (which is a function of the slope stability FS), the type of surface analyzed (e.g., circular, log spiral, two-part wedge, etc.), and the distribution of force along the length of the nails. How these factors affect the results may vary depending on the software used for the wall design. The designer should consider these factors when selecting values for T_{maxsn} to be used in the limit state equations specified in Articles 11.12.5 and 11.12.6 for designing the nails for tensile and pullout resistance, and the strength of the facing needed.

The load and resistance factors specified for use for nail pullout (Article 11.12.5.2), nail tensile resistance (Article 11.12.6.1), and facing design (Article 11.12.6.2) have been calibrated by fitting to past Allowable Stress Design (ASD) practice. For example, for ASD pullout resistance, a slope stability FS of 1.3 was used, and the nominal pullout resistance was reduced by an FS of 2.0. For the LRFD limit state equations corresponding to this example, T_{maxsn} values are obtained from the slope stability analysis using a soil failure resistance factor of 0.75 and load factor of 1.0, a load factor for vertical earth pressure applied to T_{maxsn} of $\gamma_{EV} = 1.35$, and a pullout resistance factor of 0.65. The equations produce a similar result as used in past ASD practice. Additional background information regarding the development of load and resistance factors for soil nail wall design is provided in Lazarte et al. (2015).

Figure C11.12.2-1—Failure Modes in Soil Nail Walls

11.12.3—Movement at the Service Limit State

The provisions of Articles 10.6.2.2, 10.7.2.2, and 11.8.3.1 shall apply as applicable.

The effects of wall movements on adjacent facilities shall be considered in the development of the wall design.

C11.12.3

A first order estimate of horizontal and vertical displacements at the top of the wall can be estimated with the procedure presented in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015). Displacements are a function of the soil nail length to wall height ratio, soil nail spacing, wall batter, and soil conditions.

11.12.4—Safety against Soil Failure (External and Overall Stability—Strength Limit State)

11.12.4.1—Sliding

The provisions of Article 10.6.3.4 shall apply.

11.12.4.2—Overall Stability

The potential failure surfaces to be considered in overall stability should not intersect soil nails but instead go behind the ends of the nails. With regard to the minimum level of safety required, the provisions of Article 3.4.1 for load factors and Article 11.6.3.7 for soil resistance factors shall apply. For the case of failure surfaces intersecting soil nails, see Articles 11.12.2, 11.12.5, and 11.12.6.

Overall stability analyses should also be conducted for intermediate excavation conditions. For soil nail walls with complex geometry (e.g., multiple-tiered walls), the provisions of Article 11.10.4.3 shall apply.

C11.12.4.2

Overall stability of soil nail walls is commonly evaluated using two-dimensional limit-equilibrium-based methods. For this specific limit state, only failure surfaces that are behind the soil nails are considered. Failure surfaces that intersect one or more nail rows, including both surfaces that are defined as compound stability and those that intersect all the nail rows (see Figure C11.12.2-1) are addressed in the strength limit state for internal wall stability. Detailed guidance for evaluating the overall stability of soil nail walls, including intermediate excavation conditions, and for defining nominal tensile and pullout forces in the soil nails is provided in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

11.12.5—Safety against Soil Failure (Internal and Compound Stability—Strength Limit State)

11.12.5.1—Soil Shear Strength

As specified in Article 11.12.2, limit equilibrium analyses shall be conducted to assess internal and compound stability of soil nail walls in the strength limit state. If the wall supports a structural element, the load applied to the wall by the structural element should be factored as specified in Article 3.4.1 for the Strength I limit state. With regard to the minimum level of safety required, the provisions of Article 11.6.3.7 for soil resistance factors shall apply.

11.12.5.2—Soil Nail Pullout

Soil nails shall be designed to resist pullout of the length of nail extending beyond the critical failure surface. It shall be verified that the factored pullout resistance available is sufficient to obtain the desired minimum level of safety as specified in Articles 11.12.2 and 11.12.5.1, and as further described in Articles C11.12.2 and C11.12.5.1. The following shall be verified for each row of nails, considering both internal and compound stability:

$$\phi_{PO} R_{PO} \geq \gamma_{p-EV} T_{maxsn} \quad (11.12.5.2-1)$$

where:

- R_{PO} = nominal pullout resistance (kip)
- ϕ_{PO} = resistance factor for soil nail pullout (dim.)
- γ_{p-EV} = the maximum load factor for vertical earth pressure, EV , from Table 3.4.1-2 (dim.).
- T_{maxsn} = maximum soil nail force determined from the limit equilibrium stability analysis in Article 11.12.2 (kip)

Variables for pullout are illustrated in Figure 11.12.5.2-1.

The nominal pullout resistance, R_{PO} (kips), shall be computed as:

$$R_{PO} = \pi q_u D_{DH} L_P \quad (11.12.5.2-2)$$

where:

- R_{PO} = nominal pullout resistance (kip)
- q_u = bond strength per unit area (ksf)
- D_{DH} = drill hole diameter (ft)
- L_P = the length of soil nail behind the critical failure surface (ft)

C11.12.5.1

See Article C11.12.2 for background on limit equilibrium analysis procedures for soil nail walls. As discussed in that article, the resistance of the soil (i.e., its shear strength) is handled separately from LRFD analysis of the nails.

While compound stability is in a sense both internal and external, because the failure surface involves the resistance of the structural elements (i.e., nails), this limit state is dealt with in the strength limit state. The resistance of the nails in pullout and as tensile members is assessed as specified in Articles 11.12.5.2 and 11.12.6.1.

C11.12.5.2

A uniform distribution of bond stresses along the pullout length behind the critical failure surface, L_P , is assumed.

When using the pullout limit state Eqs. 11.12.5.2-1 and 11.12.5.2-2, L_P is usually determined using the critical failure surface from the final wall configuration.

Soil nail bond strength is influenced by soil or rock type, overburden stress, drilling method, drill hole cleaning, grouting procedure, and grout characteristics. As a guide, the presumptive values in Tables C11.12.5.2-1 and C11.12.5.2-2 may be used to estimate the bond strength for different drilling methods and to estimate the bond strength for gravity-grouted in coarse-grained and fine-grained soils, respectively. Presumptive bond strength values in weathered rock and in rock, for rotary drilling method, are provided in Table C11.12.5.2-3.

Figure 11.12.5.2-1—Definition of Pullout Variables

Table C11.12.5.2-1—Presumptive Bond Strength for Soil Nails in Coarse-Grained Soils (FHWA-NHI-14-007/FHWA GEC 7, Lazarte et al., 2015; after Elias and Juran, 1991)

Drilling Method	Soil Type	Bond Strength, q_u (psi)
Rotary Drilled	Sand/Gravel	15–26
Rotary Drilled	Silty Sand	15–22
Rotary Drilled	Silt	9–11
Rotary Drilled	Piedmont Residual	6–17
Rotary Drilled	Fine Colluvium	11–22
Driven Casing	Sand/Gravel w/ low overburden ⁽¹⁾	28–35
Driven Casing	Sand/Gravel w/ high overburden ⁽¹⁾	41–62
Driven Casing	Dense Moraine	55–70
Driven Casing	Colluvium	15–26
Augered	Silty Sand Fill	3–6
Augered	Silty Fine Sand	8–13
Augered	Silty Clayey Sand	9–20

Note: (1) Low and high overburden are defined as effective overburden pressure being, respectively, less than and greater than 1.5 tsf.

Table C11.12.5.2-2—Presumptive Bond Strength for Soil Nails in Fine-Grained Soils (FHWA-NHI-14-007/FHWA GEC 7, Lazarte et al., 2015; after Elias and Juran, 1991)

Drilling Method	Soil Type	Bond Strength, q_u (psi)
Rotary Drilled	Silty Clay	5–7
Driven Casing	Clayey Silt	13–20
Augered	Loess	4–11
Augered	Soft Clay	3–4
Augered	Stiff Clay	6–9
Augered	Stiff Clayey Silt	6–15
Augered	Calcareous Sandy Clay	13–20

Table C11.12.5.2-3—Presumptive Bond Strength for Soil Nails in Rock (FHWA-NHI-14-007/FHWA GEC 7, Lazarte et al. 2015; after Elias and Juran, 1991)

Rock Type	Bond Strength, q_u (psi)
Marl/Limestone	44–58
Phyllite	15–44
Chalk	73–87
Soft Dolomite	58–87
Fissured Dolomite	87–145
Weathered Sandstone	29–44
Weathered Shale	15–22
Weathered Schist	15–25
Basalt	73–87
Slate/Hard Shale	44–58

The use of the current value of EV in Table 3.4.1-2 (referred to in this Section as γ_{p-EV}) for the load factor in this case should be considered an interim measure until research is completed to quantify load prediction bias and uncertainty.

11.12.6—Safety against Structural Failure (Internal and Compound Stability—Strength Limit State)

11.12.6.1—Soil Nail in Tension

It shall be verified that the factored soil nail tensile resistance available is sufficient to obtain the desired minimum level of safety as specified in Articles 11.12.2 and 11.12.5.1, and as further described in Articles C11.12.2 and C11.12.5.1. Therefore, the following limit state shall be verified for each row of nails, considering both internal and compound stability:

$$\phi_T R_T \geq \gamma_{p-EV} T_{maxsn} \quad (11.12.6.1-1)$$

where:

- ϕ_T = resistance factor for bar in tension from Table 11.5.7-1 (dim.)
- R_T = nominal tensile resistance of bar (kip)
- γ_{p-EV} = the maximum load factor for vertical earth pressure, EV , from Table 3.4.1-2 (dim.)
- T_{maxsn} = maximum soil nail force, determined from the limit equilibrium stability analysis in Article 11.12.2 (kip)

The nominal tensile resistance of a soil nail bar shall be computed as:

C11.12.6.1

The use of the current value of EV in Table 3.4.1-2 (referred to in this Section as γ_{p-EV}) for the load factor in this case should be considered an interim measure until research is completed to quantify load prediction bias and uncertainty.

The contribution of the grout to the nominal resistance in tension should be disregarded.

$$R_T = A_t f_y \quad (11.12.6.1-2)$$

where:

A_t = cross-sectional area of soil nail tendon (in.²)

$$f_y = \text{yield strength of steel (ksi)}$$

11.12.6.2—Soil Nail Wall Facing—Strength Limit State

11.12.6.2.1—General

The failure modes of the facing of a soil nail wall that shall be considered include: (a) flexure (i.e., bending); (b) punching shear; and (c) headed stud in tension. These failure modes are shown schematically in Figure 11.12.6.2.1-1. Nail loads used as part of the facing system analysis are determined as specified in Article 11.12.2 considering both internal and compound stability, assuming that T_{osn} , the load in the soil nail at the nail head, is equal to T_{maxsn} .

C11.12.6.2.1

The failure modes for flexure and punching shear in the facing shall be considered separately for the temporary and the permanent facing. The failure mode for tension in the headed stud shall be considered only in permanent facings.

Figure 11.12.6.2.1-1—Failure Modes to be Considered in Soil Nail Wall Facings: (a) Typical Section, (b) Flexure for Both Initial and Final Facing; (c) Punching Shear in Initial Facing; (d) Punching Shear in Final Facing; and (e) Headed stud in Tension

11.12.6.2.2—Facing Flexure

As part of the slope stability limit equilibrium analysis, as specified in Article 11.12.2 and as further described in Article C11.12.2, for flexure in the facing, the following equation shall be satisfied:

$$\phi_{FF} R_{FF} \geq \gamma_{p-EV} T_{osn} \quad (11.12.6.2.2-1)$$

in which:

- ϕ_{FF} = resistance factor for flexure in the facing from Table 11.5.7-1 (dim.)
- R_{FF} = flexural resistance of facing (kip)
- T_{osn} = tensile force at the nail head (kip)

C11.12.6.2.2

The nominal resistance for flexure in the facing depends on the soil pressures mobilized behind the facing, horizontal and vertical soil nail spacing, soil conditions, and facing stiffness. The pressure distribution acting on the facing can be nonuniform, with load concentrating near the soil nail and decreasing toward the midpoint between the nails. See Lazarte et al. (2015) for a more in-depth explanation of the pressure distribution behind the soil nail wall facing. C_F is used to account for this nonuniformity.

Reinforcement can be welded wire mesh (WWM) or concrete reinforcement bars.

See FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015) for guidance on minimum and maximum

R_{FF} shall be estimated using the following equations:

$$R_{FF} = 3.8C_F f_y F \quad (11.12.6.2.2-2)$$

This equation is valid for shotcrete with $f_c \geq 4,000$ psi.

$$F = \text{smaller of } \begin{cases} (a_{vm} + a_{vn}) \times \left(\frac{S_H}{S_V} h \right) \\ (a_{hm} + a_{hn}) \times \left(\frac{S_V}{S_H} h \right) \end{cases} \quad (11.12.6.2.2-3)$$

where:

- C_F = factor to consider nonuniform soil pressures behind soil nail wall facing (dim) see Table 11.12.6.2.2-1
- h = nominal facing thickness, h_i for initial facing or h_f for final facing (ft)
- a_{vn} = cross-sectional area of vertical reinforcement per unit width direction, at nail head (in.²/ft); see Table 11.12.6.2.2-2
- a_{vm} = cross-sectional area vertical reinforcement per unit width at midspan (in.²/ft); see Table 11.12.6.2.2-2
- a_{hn} = cross-sectional area of horizontal reinforcement per unit width at nail head (in.²/ft); see Table 11.12.6.2.2-2
- a_{hm} = cross-sectional area of horizontal reinforcement per unit width at midspan (in.²/ft); see Table 11.12.6.2.2-2

Table 11.12.6.2.2-1—Factor, C_F

Facing Layer	Nominal Facing Thickness, h_i or h_f (in.)	Factor, C_F
Initial	4	2.0
	6	1.5
	8	1.0
Final	All	1.0

The cross-sectional areas of reinforcement per unit width in the vertical or horizontal direction and around and in-between nails are shown schematically in Figure 11.12.6.2.2-1.

Reinforcement areas per unit width shall be determined as summarized in Table 11.12.6.2.2-2.

amount of steel reinforcement ratio, ρ_{ij} , expressed as a percentage, to be placed at different locations of the facing. The reinforcement ratio is defined as:

$$\rho_{ij} = \frac{a_{ij}}{0.5 h} \times 100 \quad (C11.12.6.2.2-1)$$

Where a_{ij} can take the values of a_{vm} , a_{vn} , a_{hm} , or a_{hn} ; and h can take the values of h_i or h_f .

With regard to Eqs. 11.12.6.2.2-2 and 11.12.6.2.2-3, more general equations are provided in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

Table 11.12.6.2.2-2—Facing Reinforcement Area per Unit Width

Direction	Location	Cross-Sectional Area of Reinforcement per Unit Width
Vertical	Nail Head ⁽¹⁾	$a_{vm} = a_{vm} + \frac{A'_{VN}}{S_H}$
	Midspan	a_{vm}
Horizontal	Nail Head ⁽²⁾	$a_{hm} = a_{hm} + \frac{A'_{HN}}{S_V}$
	Midspan	a_{hm}

Notes:

(1) At the nail head, the total cross-sectional area (per unit length) of reinforcement is the sum of the WWM area, a_{vm} , and the area of additional vertical bars, A'_{VN} , divided by the horizontal spacing, S_H .

(2) At the nail head, the total area is the sum of the area of the WWM, a_{hm} , and the area of additional horizontal bars (i.e., waler bars, A'_{HN}) divided by S_V .

If (vertical) bars are used behind the nail heads, the total reinforcement area per unit length in the vertical direction shall be calculated as:

$$a_{vm} = a_{vm} + \frac{A'_{VN}}{S_H} \quad (11.12.6.2.2-4)$$

where:

A'_{VN} = equivalent cross-sectional area at the head in the vertical direction (in.²)

Similarly, this concept should be applied if additional horizontal rebar (i.e., waler bars) is used. The total reinforcement area per unit length in the horizontal direction shall then be calculated as:

$$a_{hm} = a_{hm} + \frac{A'_{HN}}{S_V} \quad (11.12.6.2.2-5)$$

A'_{HN} = equivalent cross-sectional area at the head in horizontal direction (in.²)

Figure 11.12.6.2.2-1—Geometry used for Flexural Failure Mode

11.12.6.2.3—Facing Punching Shear Resistance

As part of the slope stability limit equilibrium analysis, as specified in Article 11.12.2 and as further described in Article C11.12.2, for punching shear in the facing, it shall be verified that:

$$\phi_{FP} R_{FP} \geq \gamma_{p-EV} T_{osn} \quad (11.12.6.2.3-1)$$

where:

- ϕ_{FP} = resistance factor for punching shear in facing (dim)
- R_{FP} = nominal punching shear resistance of facing (kip)

in which:

$$R_{FP} = C_p V_F \quad (11.12.6.2.3-2)$$

where:

- V_F = punching shear force acting through facing (kip)
- C_p = correction factor to account for contribution of soil support (dim). C_p should normally be assumed to be 1.0.

The nominal punching shear resistance shall be calculated as:

C11.12.6.2.3

The failure mode for punching shear may involve the formation of a localized, conical failure surface around the nail head. The failure surface may extend behind the bearing plate or headed studs and may punch through the facing thickness at an inclination of about 45 degrees and form two punching failure surfaces (see Figure 11.12.6.2.3-1).

The size of the conical failure surfaces depends on the facing thickness and the type of the nail-facing connection (e.g., bearing plate or headed studs).

Generally, the contribution from the soil support is ignored and, $C_p = 1.0$. If the soil reaction is considered, C_p can have values up to 1.15.

$$V_F = 18.34 \sqrt{f'_c} \pi D'_c h_c \quad (11.12.6.2.3-3)$$

where:

- f'_c = compressive strength of concrete (ksi)
 D'_c = effective equivalent diameter of conical surface at soil nail head (ft)
 h_c = effective depth of conical surface (ft)

For the initial facing:

$$D'_c = L_{BP} + h_c \quad (11.12.6.2.3-4)$$

where:

L_{BP} = length of the bearing plate (ft)

Typical dimensions for bearing plates and headed studs can be found in FHWA-NHI-14-007/ FHWA GEC 7 (Lazarte et al., 2015).

For the final facing:

$$D'_c = \text{smaller of } \begin{cases} S_{HS} + h_c \\ 2h_c \end{cases} \quad (11.12.6.2.3-5)$$

where:

S_{HS} = spacing of the headed studs

These equations shall be separately used to design initial and final facing. The maximum and average diameters of the failure surface (D_c and D'_c on Figure 11.12.6.2.3-1), as well as the effective depth of the failure surface, h_c , shall be selected separately for initial and final facings.

For initial facings, only the dimensions of the bearing plate and facing thickness should be considered. For final facings, the dimensions of headed studs, bearing plate, and the facing thickness shall be considered.

Figure 11.12.6.2.3-1—Punching Shear Failure Modes

11.12.6.2.4—Headed Stud in Tension

As part of the slope stability limit equilibrium analysis, as specified in Article 11.12.2 and as further described in Article C11.2.2, for design of the facing headed stud in tension, it shall be verified that:

$$\phi_{FH} R_{FH} \geq \gamma_{p-EV} T_{osn} \quad (11.12.6.2.4-1)$$

where:

- ϕ_{FH} = resistance factor for headed stud in tension (dim)
- R_{FH} = nominal tensile resistance of headed stud (kip)

C11.12.6.2.4

To provide sufficient anchorage, the length of the headed studs shall extend beyond the midsection of the facing, while maintaining 2.0 in. minimum cover.

When threaded bolts are used in lieu of headed stud connectors, the effective cross-sectional area of the bolts must be employed in Eqs. 11.12.6.2.4-2, 11.12.6.2.4-3, and 11.12.6.2.4-4. See FHWA-NHI-14-007/ FHWA GEC 7 (Lazarte et al., 2015) for computation of the effective cross-sectional area of threaded anchors.

in which:

$$R_{FH} = N_H A_S f_{y-hs} \quad (11.12.6.2.4-2)$$

where:

- N_H = number of headed studs in the connection (dim)
 A_S = cross-sectional area of the shaft of a headed stud (in.²)
 f_{y-hs} = minimum yield stress of headed stud (ksi)

In addition, it should be verified that:

$$A_H \geq 2.5 A_S \quad (11.12.6.2.4-3)$$

$$t_{SH} \geq 0.5 (D_{SH} - D_{SC}) \quad (11.12.6.2.4-4)$$

where (see Figure 11.12.6.2.4-1):

- A_H = cross-sectional area of the stud head (in.²)
 t_{SH} = head thickness (in.)
 D_{SH} = diameter of the stud head (in.)
 D_{SC} = diameter of the headed stud shaft (in.)

Figure 11.12.6.2.4-1—Geometry of a Headed Stud

11.12.7—Seismic Design of Soil Nail Walls

Soil nail walls shall be designed for seismic loads when applicable. Article 11.5.4.2 defines when earth-retaining structures require analysis for loads at the Extreme Event I limit state. The criteria for MSE walls, another earth-supporting system regarded as flexible, is considered appropriate for soil nail walls.

11.12.7.1—External and Global Stability

External stability of soil nail walls for seismic loading conditions shall be conducted as specified in Article 11.6.5 except as modified in Article 11.10.7.1 for MSE walls for sliding stability. For global stability, a

C11.12.7

Soil nail seismic resistance factors, for use with MSE wall seismic design criteria, are presented in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

horizontal seismic coefficient, per Article 11.6.5, shall be incorporated into the limit equilibrium analysis.

11.12.7.2—Internal Stability

Internal stability of soil nail walls for seismic loading conditions shall be performed by incorporating a horizontal seismic coefficient, per Article 11.6.5, into the limit equilibrium analysis to quantify nominal soil nail tensile load under seismic loading. Resistance factors for internal stability for seismic conditions shall be as follows:

- Bar pullout – 0.65
- Bar rupture
 - Bar grades 60–80 (AASHTO M 31M/M 31) – 0.75
 - Bar grade 150 (AASHTO M 275M/M 275) – 0.65
 - Facing flexure resistance – 0.90
 - Facing punching shear – 0.90
 - Headed stud in tension
 - A307 steel bolt – 0.65
 - A325 bolt – 0.75

11.12.8—Corrosion Protection

For all permanent soil nail walls and, in some cases, for temporary walls, the soil corrosion potential shall be evaluated and considered part of the design.

Soils shall typically be considered nonaggressive if the soils meet all of the following criteria:

- pH = 5 to 10
- Resistivity $\geq 3,000$ ohm-cm
- Chlorides ≤ 100 ppm
- Sulfates ≤ 200 ppm
- Organic Content ≤ 1 percent by weight

Soils not meeting one or more of these criteria shall be considered to be aggressive. If the resistivity is greater than or equal 5,000 ohm-cm, the chlorides and sulfates requirements may be waived.

The primary corrosion protection depends on the aggressiveness of the in-situ soils. Two classes of corrosion protection shall be used.

- Class A—Bar Encapsulation
- Class B—Epoxy-coated or galvanized bars

Class A bar encapsulation shall consist of providing either a 40-mil thickness PVC or 60-mil thickness HDPE corrugated sheath. The sheath shall have a minimum diameter of the bar plus 0.4 in. Place the sheath around the bar and grout the annular space between the bar and

C.11.12.7.2

Limit equilibrium slope stability analyses are used to quantify the nominal tensile load under seismic loads in the soil nail bars.

C11.12.8

An in-depth discussion on corrosion of metallic components used to construct soil nail walls is provided in FHWA-NHI-14-007/FHWA GEC 7 (Lazarte et al., 2015).

The criteria provided for assessing corrosion potential are based on Elias et al., 2009.

Recommended test methods for soil chemical property determination include AASHTO T 289 for pH, AASHTO T 288 for resistivity, AASHTO T 291 for chlorides, AASHTO T 290 for sulfates, and AASHTO T 267 for organics.

Resistivity should be determined under the most adverse condition (i.e., a saturated state) in order to obtain a resistivity that is independent of seasonal and other variations in soil-moisture content (Elias et al., 2009).

A nonaggressive site does not mean that no corrosion will occur. Rather, for a nonaggressive site, a tolerable level of corrosion over the life of the structure should be expected, provided that the electro-chemical characteristics of the site do not change over the life of the structure.

Class A corrosion protection is used for sites that are considered aggressive or if the electro-chemical environment is unknown or not adequately defined. Class B corrosion protection is used for sites that are considered nonaggressive. However, Class A corrosion protection

the sheath. The grout cover shall be a minimum of 0.2 in. on all sides of the bar. See Figure 11.12.8-1.

may be used for nonaggressive sites at the discretion of the Owner.

Figure 11.12.8-1—Bar Encapsulation (Lazarte et al., 2015)

Class B corrosion protection consists of epoxy coating and/or galvanization. The epoxy coating on the bars, plates, washers, and nuts shall have a required thickness ranging from 7 to 12 mils.

The other Class B corrosion protection is galvanization (i.e., zinc coating). The minimum galvanization that should be applied is 2.0 oz/ft² or 3.4-mil thickness. The galvanization of the bar shall adhere to the requirements of AASHTO M 111M/M 111 (ASTM A123/A123M). The plates, nuts, and washers shall be galvanized to the requirements of ASTM A153.

The minimum grout cover around the bar shall be 1 in. to provide a secondary level of corrosion protection. This minimum cover shall account for the sag of the bar between centralizers.

The epoxy coating is applied as required in ASTM A775 or A934.

The epoxy coatings used on the bars are color-coded green, gray, or purple. The green epoxy coating meets ASTM A775 and is used due to its flexibility. Green epoxy coating is suitable for rebar that will be bent into different shapes. The gray and purple epoxy coatings are less flexible, but have greater chemical resistance. The purple epoxy coating is better suited for marine or harsh environments.

ASTM A123 requires a minimum average galvanization thickness of 3.4 mil for all bars on the project and a minimum of 3.1 mil on any individual bar. The zinc coating provides a sacrificial anode that corrodes while protecting the base metal.

The corrosion protection indicated applies only to customary rebar used as bars. The use of high-strength bars requires project-specific corrosion projection to be developed.

The use of sacrificial steel is not recommended as a corrosion protection method. However, if the Owner wants to use sacrificial steel as a corrosion protection method, see Lazarte et al., 2015 for the procedure.

11.12.9—Soil Nail Testing

Testing of soil nails shall be conducted to verify the bond strength, q_u , and nominal load transfer rate, r_{po} , between the soil and soil nail. This testing shall consist of, as a minimum, verification tests conducted on

C11.12.9

During design, the bond strength should be estimated in accordance with Article 11.12.5.2, and as further described in Article C11.12.5.2 and used as input to conduct the soil nail wall design, from which the nail

- Pore water pressures from perched water or groundwater do not negatively affect nail performance.

If perched groundwater or the groundwater table is anticipated to be above the base of the wall, horizontal or subhorizontal drains should be used to reduce the effect of pore pressure on the stability of the wall and any impacts on the long-term performance and durability of the nails. If horizontal drains are not practical to use, then the wall shall be designed for the long-term presence of ground water in the wall, considering both wall stability and the effect of long-term water exposure on the life of the soil nails and connection to the facing.

should be used to prevent the build-up of hydrostatic pressures behind the wall facing due to incidental water and minor surface infiltration. The strip drains should be fitted with drainage elements at the bottom of the wall that allow exit of the water from the strips to the outside of the wall. Vertical strip drains should not be solely relied upon to provide complete reduction of hydrostatic pressure if perched water or elevated groundwater is present. Vertical strip drains are typically spaced at one to two times the horizontal spacing of the nails, S_h , with a spacing equal to S_H being more common. Strip drain width and spacing are commonly selected based on judgment and experience; however, the designer should consider problems with sloughing of shotcrete if not enough soil face contact area is provided.

To design a drainage system consisting of drilled horizontal or subhorizontal drains, a seepage analysis should be performed to determine the diameter, length, and spacing of drilled horizontal drains. Typically, horizontal drains are installed horizontally or with mild upslope (5–10 degrees from horizontal).

APPENDIX A11—SEISMIC DESIGN OF RETAINING STRUCTURES

A11.1—GENERAL

This Appendix provides information that supplements the provisions contained in Section 11 regarding the design of walls and freestanding abutments for seismic loads. Detailed design methodology is provided for the calculation of seismic earth pressures, both active and passive. Design methodology is also provided for the estimation of deformation effects on the seismic acceleration a wall will experience.

A11.2—PERFORMANCE OF WALLS IN PAST EARTHQUAKES

Even as early as 1970, Seed and Whitman concluded that “many walls adequately designed for static earth pressures will automatically have the capacity to withstand earthquake ground motions of substantial magnitudes and, in many cases, special seismic provisions may not be needed.” Seed and Whitman further indicated that this statement applies to gravity and semigravity walls with peak ground accelerations up to 0.25g. More recently, Bray et al. (2010) and Lew et al. (2010a and 2010b) indicate that lateral earth pressure increases due to seismic ground motion are likely insignificant for peak ground accelerations of 0.3g to 0.4g or less, indicating that walls designed to resist static loads (i.e., the strength and service limit states) will likely have adequate stability for the seismic loading case, especially considering that load and resistance factors used for Extreme Event I limit state design are at or near 1.0.

Following the 1971 San Fernando earthquake, Clough and Frigaszy (1977) assessed damage to floodway structures, consisting of reinforced concrete cantilever (vertical) walls structurally tied to a floor slab forming a continuous U-shaped structure. They found that no damage was observed where peak ground accelerations along the structures were less than 0.5g. However, damage and wall collapse was observed where accelerations were higher than 0.5g, or localized damage occurred where the structures crossed the earthquake fault. They noted that while higher strength steel rebar was used in the actual structure than required by the static design, the structure was not explicitly designed to resist seismic loads. Gazetas et al. (2004) observe that cantilever semigravity walls with little or no soil surcharge exposed to shaking in the 1999 Athens earthquake performed well for peak ground accelerations up to just under 0.5g even though the walls were not specifically designed to handle seismic loads. Lew et al. (1995) make similar observations with regard to tied back shoring walls in the 1994 Northridge earthquake and Tatsuoka et al. (1996) similarly observe good wall performance for MSE type gravity walls in the 1995 Kobe earthquake. See Bray et al. (2010), Lew et al. (2010a and 2010b), and Al Atik and Sitar (2010) for additional background on observed wall performance and the generation of seismic earth pressures.

Walls meeting the requirements in Article 11.5.4.2 that allow a seismic analysis to not be conducted have demonstrated consistently good performance in past earthquakes. For wall performance in specific earthquakes, see the following:

- Gravity and semigravity cantilever walls in the 1971 San Fernando earthquake (Clough and Fragaszy, 1977).
- Gravity and semigravity cantilever walls in the 1999 Athens earthquake (Gazetas et al., 2004).
- Soil nail walls (Vucetic et al., 1998) and MSE walls (Collin et al., 1992) in the 1989 Loma Prieta, California earthquake.
- MSE walls in the 1994 Northridge, California earthquake (Bathurst and Cai, 1995).
- MSE walls and reinforced concrete gravity walls in the 1995 Kobe, Japan earthquake (Tatsuoka et al., 1996).
- MSE walls and concrete gravity and semigravity walls in the 2010 Maule, Chile earthquake (Yen et al., 2011).
- Summary of the performance of various types of walls (Koseki et al., 2006).
- Reinforced earth walls withstand Northridge earthquake (Frankenberger et al., 1996).
- Performance of reinforced earth structures in the vicinity of Kobe during the Great Hanshin earthquake (Kobayashi et al., 1996).
- Evaluation of seismic performance in MSE structures (Sankey et al., 2001).

However, there have been some notable wall failures in past earthquakes. For example, Seed and Whitman (1970) indicate that some concrete gravity walls and quay walls (both gravity structures and anchored sheet pile nongravity cantilever walls), in the great Chilean earthquake of 1960 and in the Niigata, Japan earthquake of 1964, suffered severe displacements or even complete collapse. In most of those cases, significant liquefaction behind or beneath the wall was the likely cause of the failure. Hence, Article 11.5.4.2 specifies that a seismic analysis should be performed if liquefaction or severe strength loss in sensitive clays can cause instability of the wall. Seed and Whitman (1970) indicate, however, that collapse of walls located above the water table has been an infrequent occurrence.

Tatsuoka et al. (1996) indicated that several of the very old (1920s to 1960s) unreinforced masonry gravity walls and concrete gravity structures exposed to strong shaking in the 1995 Kobe, Japan earthquake did collapse. In those

cases, collapse was likely due to the presence of weak foundation soils that had inadequate bearing and sliding resistance and, in a few cases, due to the presence of a very steep sloping surcharge (e.g., 1.5H:1V) combined with poor soil conditions. Soil liquefaction may have been a contributing factor in some of those cases. These wall collapses were mostly located in the most severely shaken areas (e.g., as high as 0.6g to 0.8g). As noted previously, Clough and Frigaszy (1977) observe concrete cantilever walls supporting open channel floodways that had collapsed where peak ground accelerations were 0.5g or more in the 1971 San Fernando earthquake. However, in that case, soil conditions were good. All of these wall cases where collapse or severe damage/deformations occurred are well outside of the conditions and situations where Article 11.5.4.2 allows the seismic design of walls to be waived.

Setting the limit at 0.4g for the Article 11.5.4.2 no seismic analysis provision represents a reasonable compromise between observations from laboratory modeling and full-scale wall situations (i.e., lab modeling indicates that seismic earth pressures are very low, below 0.4g, and walls in actual earthquakes start to have serious problems, including collapses even in relatively good soils, when the acceleration is greater than 0.5g and the wall has not been designed for the full seismic loading). However, if soil strength loss and flow due liquefaction or strength loss in sensitive silts and clays occurs, wall collapse can occur at lower acceleration values. Note that for the lab model studies, the 0.4g limit represents the limit at which significant seismic earth pressure does not appear to develop. However, for walls with a significant structural mass, the inertial force on the wall mass itself can still occur at accelerations less than 0.4g. At 0.4g, the combination of seismic earth pressure and wall inertial force is likely small enough still to not control the forces in the wall and its stability, provided the wall mass is not large. For typical gravity walls, the wall mass would not be large enough to offset the lack of seismically increased earth pressure below 0.4g. A possible exception regarding wall mass inertial forces is reinforced soil walls, though that inertial mass consists of soil within the reinforced soil zone. However, due to their flexibility, reinforced soil walls perform better than reinforced concrete walls, so the inertial mass issue may not be as important for that type of wall. Note that experience with walls in actual earthquakes in which the walls have not been designed for seismic loads is limited. So, while all indications are that major wall problems do not happen until the acceleration is greater than A_s of 0.5g, the majority of those walls where such observations could be made have been strengthened to resist some degree of seismic loading. If walls are not designed for seismic loads, it is reasonable to back off a bit from the observed 0.5g threshold. Hence, 0.4g represents a reasonable buffer relative to potential severe wall damage or collapse as observed for walls in earthquakes at 0.5g or more.

Based on previous experience, walls that form tunnel portals have tended to exhibit more damage due to earthquakes than freestanding walls. It is likely that the presence of the tunnel restricts the ability of the portal wall to move, increasing the seismic forces to which the wall is subjected. Hence, a seismic design is recommended in such cases.

A11.3—CALCULATION OF SEISMIC ACTIVE PRESSURE

Seismic active earth pressures have historically been estimated using the M–O Method. However, this method is not applicable in some situations. More recently, Anderson et al. (2008) have suggested a GLE method that is more broadly applicable. Both methods are provided herein. Specifications which should be used to select which method to use are provided in Article 11.6.5.3.

A11.3.1—M–O Method

The method most frequently used for the calculation of the seismic soil forces acting on a bridge abutment or freestanding wall is a pseudostatic approach developed in the 1920s by Mononobe (1929) and Okabe (1926). The M–O analysis is an extension of the Coulomb sliding-wedge theory, taking into account horizontal and vertical inertia forces acting on the soil. The analysis is described in detail by Seed and Whitman (1970) and Richards and Elms (1979). The following assumptions are made:

1. The abutment is free to yield sufficiently to enable full soil strength or active pressure conditions to be mobilized. If the abutment is rigidly fixed and unable to move, the soil forces will be much higher than those predicted by the M–O analysis.
2. The backfill is cohesionless, with a friction angle of ϕ .
3. The backfill is unsaturated, so that liquefaction problems will not arise.

The M–O Method is illustrated in Figure A11.3.1-1 and the equation used to calculate K_{AE} follows the figure.

Figure A11.3.1-1—M-O Method Force Diagrams

$$K_{AE} = \frac{\cos^2(\phi - \theta_{MO} - \beta)}{\cos \theta_{MO} \cos^2 \beta \cos(\delta + \beta + \theta_{MO})} \times \left[1 + \sqrt{\frac{\sin(\phi + \delta) \sin(\phi - \theta_{MO} - i)}{\cos(\delta + \beta + \theta_{MO}) \cos(i - \beta)}} \right]^{-2} \quad (\text{A11.3.1-1})$$

where:

- K_{AE} = seismic active earth pressure coefficient (dim)
- γ = unit weight of soil (kcf)
- H = height of wall (ft)
- h = vertical distance between ground surface and wall base at the back of wall heel (ft)
- ϕ_f = friction angle of soil (degrees)
- θ_{MO} = $\arctan[k_h/(1 - k_v)]$ (degrees)
- δ = wall backfill interface friction angle (degrees)
- k_h = horizontal seismic acceleration coefficient (dim.)
- k_v = vertical seismic acceleration coefficient (dim.)
- i = backfill slope angle (degrees)
- β = slope of wall to the vertical, negative as shown (degrees)

In discussion of the M-O Method to follow, H and h should be considered interchangeable, depending on the type of wall under consideration (see Figure A11.3.1-1).

Mononobe and Matsuo (1932) originally suggested that the resultant of the active earth pressure during seismic loading remain the same as for when only static forces are present (i.e., $H/3$ or $h/3$). However, theoretical considerations by Wood (1973), who found that the resultant of the dynamic pressure acted approximately at midheight and empirical considerations from model studies summarized by Seed and Whitman (1970) who suggested that h_a could be obtained by assuming that the static component of the soil force acts at $H/3$ from the bottom of the wall and the additional dynamic effect acts at a height of $0.6H$, resulted in increasing the height of the resultant location above the wall base. Therefore, in past practice, designers have typically assumed that $h_a = H/2$ with a uniformly distributed pressure. Note that if the wall has a protruding heel or if the wall is an MSE wall, then replace H with h in the preceding discussion.

Back analysis of full-scale walls in earthquakes, however, indicates earth pressure resultants located higher than $h/3$ will overestimate the force, resulting in a prediction of wall failure when in reality the wall performed well (Clough and Frigaszy, 1977). Recent research indicates the location of the resultant of the total earth pressure (static plus seismic) should be located one-third up from the wall based on centrifuge model tests on gravity walls (Al Atik and Sitar, 2010)

(Bray et al., 2010) (Lew et al., 2010). However, work by others (Nakamura, 2006) also indicates that the resultant location could be slightly higher, depending on the specifics of the ground motion and the wall details.

A reasonable approach is to assume that for routine walls, the combined static/seismic resultant should be located at the same location as static earth pressure resultant but no less than $h/3$. Because there is limited evidence that in some cases the combined static/seismic resultant location could be slightly higher than the static earth pressure resultant, a slightly higher resultant location (e.g., $0.4h$ to $0.5h$) for seismic design of walls for which the impact of wall failure is relatively high should be considered. However, for routine wall designs, a combined static/seismic resultant location equal to that used for static design (e.g., $h/3$) is sufficient.

The effects of abutment inertia are not taken into account in the M–O analysis. Many current procedures assume that the inertia forces due to the mass of the abutment itself may be neglected in considering seismic behavior and seismic design. This is not a conservative assumption, and for those abutments relying on their mass for stability, it is also an unreasonable assumption in that to neglect the mass is to neglect a major aspect of their behavior. The effects of wall inertia are discussed further by Richards and Elms (1979), who show that wall inertia forces should not be neglected in the design of gravity-retaining walls.

A11.3.2—Modification of M–O Method to Consider Cohesion

The M–O equation for seismic active earth pressure determination has many limitations, as discussed in Anderson et al. (2008). These limitations include the inability to account for cohesion that occurs in the soil. This limitation has been addressed by rederiving the seismic active earth pressure using a Coulomb-type wedge analysis. Generally, soils with more than 15 percent fines content can be assumed to be undrained during seismic loading. For this loading condition, total stress soil parameters, γ and c , should be used.

Eq. A11.3.2-1 provided by Anderson et al. (2008), and Figure A11.3.2-1 shows the terms in the equation. This equation is very simple and practical for the design of the retaining walls and the equation has been calibrated with slope stability computer programs.

$$P_{AE} = \frac{W[(1-k_v)\tan(\alpha-\phi)+k_h]-CL[\sin\alpha\tan(\alpha-\phi)+\cos\alpha]-C_A H[\tan(\alpha-\phi)\cos\omega+\sin\omega]}{[1+\tan(\delta+\omega)\tan(\alpha-\phi)]*\cos(\delta+\omega)} \quad (\text{A11.3.2-1})$$

The only variables in Eq. A11.3.2-1 are the failure plane angle, α , and the trial wedge surface length, L . Values of friction angle, ϕ , seismic horizontal coefficient, k_h , seismic vertical coefficient, k_v , soil cohesion, C , soil wall adhesion, C_A , soil wall friction, δ , and soil wall angle, ω , are defined by the designer on the basis of the site conditions and the U.S. Geological Survey seismic hazard maps shown in Section 3.

The recommended approach in this Section is to assume that $k_v = 0$, and $k_h = A_s$ (i.e., A_s , k_{h0} , or k_h , or some combination thereof, if the wall is greater than 20.0 ft in height and horizontal wall displacement can occur and is acceptable). A 50 percent reduction in the resulting seismic coefficient is used when defining k_h if 1.0 to 2.0 in. of permanent ground deformation is permitted during the design seismic event. Otherwise, the peak ground acceleration coefficient should be used. Eq. A11.3.2-1 can be easily calculated in a spreadsheet. Using a simple spreadsheet, the user can search for the angle, α , and calculate maximum value of P_{AE} .

Figure A11.3.2-1—Active Seismic Wedge

The following charts were developed using Eq. A11.3.2-1. These charts are based on level ground behind the wall and a wall friction, δ , of 0.67ϕ . Generally, for active pressure determination, the wall interface friction has a minor effect on the seismic pressure coefficient. However, Eq. A11.3.2-1, the GLE method, or the charts can be rederived for the specific interface wall friction if this effect is of concern or interest.

Figure A11.3.2-2—Seismic Active Earth Pressure Coefficient for $\phi = 30$ degrees (c = Soil Cohesion, γ = Soil Unit Weight, and H = Retaining Wall Height)

Note: $k_h = A_s = k_{h0}$ for wall heights greater than 20.0 ft. This could be H or h as defined in Figure A11.3.1-1.

Figure A11.3.2-3—Seismic Active Earth Pressure Coefficient for $\phi = 35$ degrees (c = Soil Cohesion, γ = Soil Unit Weight, and H = Retaining Wall Height)

Figure A11.3.2-4—Seismic Active Earth Pressure Coefficient for $\phi = 40$ degrees (c = Soil Cohesion, γ = Soil Unit Weight, and H = Retaining Wall Height)

A11.3.3—GLE Method

In some situations, the M–O equation is not suitable due to the geometry of the backfill, the angle of the failure surface relative to the cut slope behind the wall, the magnitude of ground shaking, or some combination of these factors (see Article C11.6.5.3). In such situations, a GLE method involving the use of a computer program for slope stability is likely to be more suitable for determining the earth pressures required for retaining wall design.

Steps in GLE analysis are as follows:

- Set up the model geometry, groundwater profile, and design soil properties. The internal vertical face at the wall heel or the plane where the earth pressure needs to be calculated should be modeled as a free boundary.
- Choose an appropriate slope stability analysis method. Spencer's method generally yields good results because it satisfies the equilibrium of forces and moments.
- Choose an appropriate sliding surface search scheme. Circular, linear, multi-linear, or random surfaces can be examined in many commercial slope stability analysis programs.
- Apply the earth pressure as a boundary force on the face of the retained soil. For seismic cases, the location of the force may be initially assumed at $1/3H$ of the retained soil. However, different application points between $1/3H$ and $0.6H$ from the base may be examined to determine the maximum seismic earth pressure force. The angle of applied force depends on assumed friction angle between the wall and the fill soil (typically $2/3 \phi_f$ for rigid gravity walls) or the fill friction angle (semigravity walls). If static (i.e., nonseismic) forces are also needed, the location of the static force is assumed at one-third from base ($1/3H$, where H is retained soil height).
- Search for the load location and failure surface giving the maximum load for limiting equilibrium (capacity-to-demand ratio of 1.0, i.e., $FS = 1.0$).
- Verify design assumptions and material properties by examining the loads on individual slices in the output as needed.

Additional discussion and guidance regarding this approach is provided in NCHRP Report 611 (Anderson et al., 2008).

A11.4—SEISMIC PASSIVE PRESSURE

This Article provides charts for determination of seismic passive earth pressures coefficients for a soil with both cohesion and friction based on the log spiral method. These charts were developed using a pseudostatic equilibrium method reported in Anderson et al. (2008). The method includes inertial forces within the soil mass, as well as variable soil surface geometries and loads.

Equations used in this approach are given below. Figure A11.4-1 defines the terms used in the equation.

$$dE_i = \frac{W_i(1 - K_v)[\tan(\alpha_i + \phi) - K_h] + C L_i [\sin \alpha_i \tan(\alpha_i + \phi) + \cos \alpha_i]}{[1 - \tan \delta_i \tan(\alpha_i - \phi)] \cos \delta_i} \quad (\text{A11.4-1})$$

$$P_{pn} = \frac{\sum_i dE}{[1 - \tan \delta_w \tan(\alpha_w - \phi)] \cos \delta_w} \quad (\text{A11.4-2})$$

$$K_{pn} = \frac{2P_p}{\gamma h^2} \quad (\text{A11.4-3})$$

where ϕ is the soil friction angle, c is the cohesion, and δ is wall interface friction.

Figure A11.4-2—Seismic Passive Earth Pressure Coefficient Based on Log Spiral Procedure for $c/\gamma H = 0$ and 0.05 (c = Soil Cohesion, γ = Soil Unit Weight, and H = Height or Depth of Wall Over Which the Passive Resistance Acts)

Note: $k_h = A_s = k_{ho}$ for wall heights greater than 20.0 ft.

Figure A11.4-3—Seismic Passive Earth Pressure Coefficient Based on Log Spiral Procedure for $c/\gamma H = 0.1$ and 0.15 (c = Soil Cohesion, γ = Soil Unit Weight, and H = Retaining Wall Height or Depth of Wall Over Which the Passive Resistance Acts)

$$c/\gamma H = 0.2$$

$$c/\gamma H = 0.25$$

Figure A11.4-4—Seismic Passive Earth Pressure Coefficient Based on Log Spiral Procedure for $c/\gamma H = 0.2$ and 0.25 (c = Soil Cohesion, γ = Soil Unit Weight, and H = Retaining Wall Height or Depth of Wall Over Which the Passive Resistance Acts)

A11.5—ESTIMATING WALL SEISMIC ACCELERATION CONSIDERING WAVE SCATTERING AND WALL DISPLACEMENT

The seismic acceleration acting on a wall during an earthquake is affected by both wave scattering and wall displacement (see Articles 11.6.5.2 and C11.6.5.2).

With regard to the effects of wall deformation during shaking, the Newmark sliding block concept (Newmark, 1965) was originally developed to evaluate seismic slope stability in terms of earthquake-induced slope displacement as opposed to a factor of safety against yield under peak slope accelerations. The concept is illustrated in Figure A11.5-1, where a double integration procedure on accelerations exceeding the yield acceleration of the slope leads to an accumulated downslope displacement.

The concept of allowing gravity walls to slide during earthquake loading and displacement-based design (i.e., using a Newmark sliding block analysis to compute displacements when accelerations exceed the horizontal limit equilibrium yield acceleration for the wall–backfill system) was introduced by Richards and Elms (1979). Based on this concept, Elms and Martin (1979) suggested that a design acceleration coefficient of 0.5 would be adequate for limit equilibrium pseudostatic design, provided allowance be made for a horizontal wall displacement of 10 *PGA*, in inches. The *PGA* term in Elms and Martin is equivalent to A_s or k_{h0} in these Specifications.

For many situations, Newmark analysis or simplifications of it (e.g., displacement design charts or equations based on the Newmark analysis method for certain typical cases, or the use of $k_h = 0.5k_{h0}$) are sufficiently accurate. However, as the complexity of the site or the wall–soil system increases, more rigorous numerical modeling methods may become necessary.

Figure A11.5-1—Newmark Sliding Block Concept (after Anderson, et al. 2008)

To assess the effects of wave scattering and lateral deformation on the design acceleration coefficient, k_h , three simplified design procedures to estimate the acceleration coefficient are provided in detail in the subarticles that follow. The first method (Kavazanjian et al., 1997) does not directly address wave scattering and, since wave scattering tends to reduce the acceleration, the first method is likely conservative. The second and third methods account for both wave scattering and wall deformation but are considerably more complex than the first method. With regard to estimation of wave scattering effects, the second method (Anderson et al., 2008) uses a simplified model that considers the effect of the soil mass, but not specifically the effect of the wall as a structure, whereas the third method (Bray et al., 2010) provides a simplified response spectra for the wall, considering the wall to be a structure with a fundamental period. With regard to the effect of lateral wall deformation on the wall acceleration, both methods are based on many Newmark analyses, using those analyses to develop empirical relationships between the yield acceleration for the wall and the soil it retains and the amount of deformation that occurs. The Anderson et al. (2008) method estimates the wall deformation for input yield acceleration, peak ground acceleration, and peak ground velocity (*PGV*), whereas the third method (Bray et al., 2010) estimates the reduced acceleration, k_h , for a specified deformation and spectral acceleration at a specified period. The three alternative design procedures should not be mixed together in any way.

A11.5.1—Kavazanjian et al. (1997)

Kavazanjian et al. (1997) provided the following simplified relationship based on Newmark sliding analysis, assuming that the velocity, in the absence of information on the time history of the ground motion, is equal to $30A$:

$$k_h = 0.74 A_s \left(\frac{A_s}{d} \right)^{0.25} \quad (\text{A11.5.1-1})$$

where:

- A_s = S_a at a period of zero seconds (dim.)
 k_h = horizontal seismic acceleration coefficient (dim.)
 d = lateral wall displacement (in.)

This equation should not be used for displacements of less than 1.0 in. or greater than approximately 8 in., as this equation is an approximation of a more rigorous Newmark analysis. However, the amount of deformation which is tolerable will depend on the nature of the wall and what it supports, as well as what is in front of the wall. This method may be more conservative than the more complex methods that follow. Note that this method does not address wave scattering within the wall, which in most cases will be conservative.

A11.5.2—NCHRP Report 611—Anderson et al. (2008)

For values of h (as defined in Article 11.6.5.2.2) greater than 20.0 ft but less than 60.0 ft, the seismic coefficient used to compute lateral loads acting on a freestanding retaining wall may be modified to account for the effects of spatially varying ground motions behind the wall, using the following equation:

$$k_h = \alpha k_{h0} \quad (\text{A11.5.2-1})$$

where:

- K_{h0} = αk_{h0}
 α = wall height acceleration reduction factor to account for wave scattering

For Site Class C, D, and E:

$$\alpha = 1 + 0.01h(0.5\beta - 1) \quad (\text{A11.5.2-2})$$

where:

- h = vertical distance between ground surface and wall base at the back of wall heel (ft)
 β = S_1 / k_{h0}
 S_1 = S_a value at a period of 1 s

For Site Classes A and B (hard and soft rock foundation soils), note that k_{h0} is increased by a factor of 1.2 as specified in Article 11.6.5.2.1. Eq. A11.5.2-1 provides the value of k_h if only wave scattering is considered and not lateral wall displacement.

For wall heights greater than 60.0 ft, special seismic design studies involving the use of dynamic numerical models should be conducted. These special studies are required in view of the potential consequences of failure of these very tall walls, as well as limitations in the simplified wave scattering methodology.

The basis for the height-dependent reduction factor described above is related to the response of the soil mass behind the retaining wall. Common practice in selecting the seismic coefficient for retaining wall design has been to assume rigid body soil response in the backfill behind a retaining wall. In this approach the horizontal seismic coefficient, k_{h0} , is assumed equal to A_s when evaluating lateral forces acting on an active pressure failure zone. Whereas this assumption may be reasonable for wall heights less than about 20.0 ft, for higher walls, the magnitude of accelerations in soils behind the wall will vary spatially as shown schematically in Figure A11.5.2-1.

The nature and variation of the ground motions within a wall is complex and could be influenced by the dynamic response of the wall-soil system to the input earthquake ground motions. In addition to wall height, the acceleration distribution will depend on factors such as the frequency characteristics of the input ground motions, the stiffness contrast between backfill and foundation soils, the overall stiffness and damping characteristics of the wall, and wall slope. From a design standpoint, the net effect of the spatially varying ground motions can be represented by an averaging process over a potential active pressure zone, leading to a time history of average acceleration and hence a maximum average acceleration or seismic coefficient as shown in Figure A11.5.2-1.

To evaluate this averaging process, the results of a series of analytical studies are documented in NCHRP Report 611 (Anderson et al., 2008). An evaluation of these results forms the basis for the simplified Eqs. A11.5.2-1 and A11.5.2-2. The analytical studies included wave scattering analyses assuming elastic soil media using different slope heights, with slopes ranging from near vertical for short walls to significantly battered for tall walls, as well as slopes more typical of embankments (3H:1V) and with a range of earthquake time histories. The properties of the continuum used for these analyses were uniform throughout and therefore did not consider the potential effect of impedance contrasts between different materials (i.e., the properties of the wall vs. that of the surrounding soil). The acceleration time histories simulated spectral shapes representative of Western United States (WUS) and Central and Eastern United States (CEUS) sites and reflected different earthquake magnitudes and site conditions.

Additional height-dependent, one-dimensional SHAKE (Schnaebel et al., 1972) analyses were also conducted to evaluate the influence of nonlinear soil behavior and stiffness contrasts between backfill and foundation soils. These studies were also calibrated against finite element studies for MSE walls documented by Segrestin and Bastick (1988), which form the basis for the average maximum acceleration equation (a function of A_s) given in previous editions of these Specifications prior to the 7th. The results of these studies demonstrate that the ratio of the maximum average seismic coefficient, k_h , to A_s (the α factor) is primarily dependent on the wall or slope height and the shape of the acceleration spectra (the β factor). The acceleration level has a lesser effect.

Figure A11.5.2-1—Average Seismic Coefficient Concept (after Anderson, et al., 2008)

Sliding block displacement analyses were conducted as part of NCHRP Report 611 (Anderson et al., 2008) using an extensive database of earthquake records. The objective of these analyses was to establish updated relationships between wall displacement, d , and the following three terms: the ratio k_y/k_{h0} , k_{h0} as determined in Article 11.6.5.2.1, and PGV . Two broad groups of ground motions were used to develop these equations, CEUS and WUS, as shown in Figure A11.5.2-2 (Anderson et al., 2008). Regressions of those analyses result in the following equations that can be used to estimate the relationship between wall displacement and acceleration.

Figure A11.5.2-2—Boundary between WUS and CEUS Ground Motions

For all sites except CEUS rock sites (Categories A and B), the mean displacement (in.) for a given yield acceleration may be estimated as:

$$\log d = -1.51 - 0.74 \log \left(\frac{k_y}{k_{h0}} \right) + 3.27 \log \left(1 - \frac{k_y}{k_{h0}} \right) - 0.80 \log k_{h0} + 1.59 \log (PGV) \quad (\text{A11.5.2-3})$$

where:

k_y = yield acceleration

For CEUS rock sites (Categories A and B), this mean displacement (in.) may be estimated as:

$$\log d = -1.31 - 0.93 \log \left(\frac{k_y}{k_{h0}} \right) + 4.52 \log \left(1 - \frac{k_y}{k_{h0}} \right) - 0.46 \log (k_{h0}) + 1.12 \log (PGV) \quad (\text{A11.5.2-4})$$

Note that the above displacement equations represent mean values.

In Eqs. A11.5.2-3 and A11.5.2-4, it is necessary to estimate the PGV and the yield acceleration, k_y . Values of PGV may be determined using the following correlation between PGV and spectral ordinates at 1 s, S_1 .

$$PGV (\text{in./sec}) = 38S_1 \quad (\text{A11.5.2-5})$$

where S_1 is the spectral acceleration coefficient at 1 s.

The development of the PGV - S_1 correlation is based on a simplification of regression analyses conducted on an extensive earthquake database established from recorded and synthetic accelerograms representative of both rock and soil conditions for WUS and CEUS. The study is described in NCHRP Report 611 (Anderson et al., 2008). It was found that earthquake magnitude need not be explicitly included in the correlation, as its influence on PGV is captured by its influence on the value of S_1 . The equation is based on the mean from the simplification of the regression analysis.

Values of the yield acceleration, k_y , can be established by computing the seismic coefficient for global stability that results in a capacity-to-demand (C/D) ratio of 1.0 (i.e., for overall stability of the wall/slope, $FS = 1.0$). A conventional slope stability program is normally used to determine the yield acceleration. For these analyses, the total stress (undrained) strength parameters of the soil should usually be used in the stability analysis. See guidance on the use of soil cohesion for seismic analyses discussed in Article 11.6.5.3 and its commentary.

Once k_y is determined, the combined effect of wave scattering and lateral wall displacement, d , on k_h is determined as follows:

$$k_h = \alpha k_y \quad (\text{A11.5.2-6})$$

APPENDIX B11—DETERMINATION OF T_{MAX} FOR MSE WALLS USING THE SIMPLIFIED METHOD

B11.1—GENERAL

This Appendix provides the procedures and requirements to determine the MSE wall reinforcement layer load, T_{max} , using the Simplified Method. Development of the Simplified Method is described in Allen et al. (2001).

B11.2—DETERMINATION OF T_{MAX}

For the Simplified Method, the load in the reinforcements shall be obtained by multiplying the vertical earth pressure at the reinforcement layer level by an empirically adjusted lateral earth pressure coefficient, and applying the resulting lateral pressure to the tributary layer thickness for the reinforcement to estimate the reinforcement load, T_{max} . The vertical earth pressure at each reinforcement layer level shall be the sum of the soil self-weight plus any surcharge present.

The reinforcement load, T_{max} , at each reinforcement level shall be determined as:

$$T_{max} = S_v k_r (\gamma_r Z + \gamma_f S) \quad (B11.2-1)$$

where:

- S_v = tributary vertical thickness for reinforcement layer as specified in Article 11.10.6.2.1b (ft)
- k_r = horizontal pressure coefficient of reinforced fill determined using Figure B11.2-1 (dim.)
- Z = depth of reinforcement layer below wall top (ft)
- γ_r = unit weight of soil in wall reinforcement zone (lbs/ft³)
- S = average soil surcharge thickness over reinforcement within $0.7H$ of the wall face (ft)
- γ_f = unit weight of soil in wall in surcharge above wall (lbs/ft³)

Vertical stress for maximum reinforcement load calculations shall be determined as shown in Figures 11.10.6.2.1a-1 and 11.10.6.2.1a-2. Live load is not included in the vertical stress calculation to determine T_{max} for assessing pullout loads when using the Simplified Method.

For design, the load factor applied to T_{max} for the strength limit state, γ_{p-EV} , shall be 1.35 as specified in Table 3.4.1-2, and for other loads shall be as specified in Article 3.4.1. Resistance factors for design of steel reinforced MSE walls shall be as specified in Articles 11.5.7 and 11.5.8. For geosynthetic walls, the resistance factor for both pullout and tensile resistance for the strength limit state shall be 0.9. For the Extreme Event I limit state (i.e., seismic), the resistance factor for geosynthetic reinforcement tensile and pullout resistance shall be 1.2.

The value of k_a shall be determined as specified in Articles 11.10.6.2.1c and C11.10.6.2.1c, specifically Eqs. C11.10.6.2.1c-1 and C11.10.6.2.1c-2. The horizontal pressure coefficient, k_r , is determined by applying a multiplier to the active earth pressure coefficient, k_a . The k_a multiplier for the Simplified Method shall be determined as shown in Figure B11.2-1. For assessment of reinforcement pullout, the Simplified Method multiplier for steel strip walls shall be used for all steel reinforced walls. For reinforcement rupture, the multiplier applicable to the specific type of steel reinforcement shall be used. Based on Figure B11.2-1, the k_a multiplier is a function of the reinforcement type and the depth of the reinforcement below the wall top.

Since the lateral stress ratios in this figure have been empirically derived, these values should not be used for wall design cases that are beyond their empirical basis. For design situations that are beyond the empirical basis for this method, see Article C11.10.6.2.1 for additional evaluations that should be considered.

Figure B11.2-1—Variation of the Coefficient of Lateral Stress Ratio, k_r/k_a , with Depth in a Mechanically-Stabilized Earth Wall

The reinforcement shall be designed for pullout, and reinforcement and connection rupture as specified in Articles 11.10.6.3 and 11.10.6.4, respectively. If live load is present, due to the difference in load factors for soil self-weight and live load, $\gamma_{p-EV}T_{max}$ in Eqs. 11.10.6.3.2-1 and 11.10.6.4.1-1 shall be replaced with T_{totalf} , calculated as follows when using the simplified method:

$$T_{totalf} = \gamma_{p-EV}T_{max} + \gamma_{LS}S_v k_r \gamma_f h_{eq} < \phi T_{af} R_c \quad (B11.2-2)$$

where:

- T_{totalf} = total factored load for each reinforcement layer (lbs/ft)
- T_{max} = applied load to the reinforcement, determined using Eq. B11.2-1 (kips/ft)
- γ_{p-EV} = load factor for vertical earth pressure, specified in Table 3.4.1-2 (dim.)
- ϕ = resistance factor for reinforcement tension, specified in Table 11.5.7-1 (dim.)
- T_{af} = nominal long-term reinforcement strength (kips/ft)
- R_c = reinforcement coverage ratio, specified in Article 11.10.6.4.1 (dim.)
- γ_{LS} = load factor for live load surcharge, LS (dim.)
- γ_f = unit weight of soil used to calculate live load surcharge, LS (lbs/ft³)
- h_{eq} = equivalent height of soil for live load surcharge, as specified in Article 3.11.6.4 (ft)

Similarly, at the facing connection, $\gamma_{p-EV}T_o$ shall be replaced with $T_{totalfo}$ calculated as follows when using the Simplified Method:

$$T_{totalfo} = \gamma_{p-EV}T_o + (\gamma_{LS})\gamma_f h_{eq} < \phi T_{af} R_c \quad (B11.2-3)$$

where:

- T_o = applied load at reinforcement/facing connection specified in Article 11.10.6.2.2 (kips/ft)

For more complex loading situations, such as due to the presence of concentrated loads due to foundations located on top of or within the reinforced soil and traffic barrier impact forces, replace T_{max} and T_o with T_{totalf} and $T_{totalfo}$, respectively, as specified in Article 11.10.10, using k_r determined from Figure B11.2-1.

This page intentionally left blank.

SECTION 12

BURIED STRUCTURES AND TUNNEL LINERS

Commentary is opposite the text it annotates.

12.1—SCOPE

This Section provides requirements for the selection of structural properties and dimensions of buried structures, e.g., culverts, and steel plate used to support tunnel excavations in soil.

Buried structure systems considered herein are metal pipe, structural plate pipe, long-span structural plate, deep corrugated plate, structural plate box, reinforced concrete pipe, reinforced concrete cast-in-place and precast arch, box and elliptical structures, thermoplastic pipe, and fiberglass pipe.

The type of liner plate considered is cold-formed steel panels.

C12.1

For buried structures, refer to Article 2.6.6 and the *AASHTO Drainage Manual* (2014) for hydraulic design considerations and for design methods related to location, length, and waterway openings.

Thermoplastic and fiberglass pipe are flexible plastic pipes that have similarities in installation and design; however, not all thermoplastic pipe design and installation specifications are applicable to fiberglass pipe. Fiberglass pipe is a smooth-walled thermoset resin pipe that relies on composite glass fiber within its wall for strength; thermoplastic pipe can have either solid or profile walls of homogenous material. The design specifications for fiberglass pipe are contained in Article 12.15 with reference to applicable sections from the thermoplastic pipe design specifications. Construction specifications for fiberglass pipe are included in the *AASHTO LRFD Bridge Construction Specifications*, Section 30, with the provisions for thermoplastic pipe applicable to fiberglass pipe installations except as noted.

12.2—DEFINITIONS

Abrasion—Loss of section or coating of a culvert by the mechanical action of water conveying suspended bed load of sand, gravel, and cobble-size particles at high velocities with appreciable turbulence.

Buried Structure—A generic term for a structure built by embankment or trench methods.

Corrosion—Loss of section or coating of a buried structure by chemical and/or electrochemical processes.

Culvert—A curved or rectangular buried conduit for conveyance of water, vehicles, utilities, or pedestrians.

Culvert Material Service Life—The time duration for a material that can satisfy the structural loading, hydraulic loading, and joint performance for the culvert service life duration.

Culvert Service Life—The time duration during which a culvert is expected to provide the desired function with a specified level of maintenance established at the design or retrofit stage.

Deep Corrugated Plate—Structural Plate in AASHTO M 167/M 167 with a corrugation depth greater than 5.0 in.

FEM—Finite Element Method.

Narrow Trench Width—The outside span of rigid pipe, plus 1.0 ft.

Projection Ratio—Ratio of the vertical distance between the outside top of the pipe and the ground or bedding surface to the outside vertical height of the pipe, applicable to reinforced concrete pipe only.

Side Radius—For deep corrugated plate structures, the side radius is the radius of the plate in the section adjacent to crown (top) section of the structure. In box-shaped structures, this is often called the haunch radius.

Soil Envelope—Zone of controlled soil backfill around culvert structure required to ensure anticipated performance based on soil-structure interaction considerations.

Soil-Structure Interaction System—A buried structure whose structural behavior is influenced by interaction with the soil envelope.

Tunnel—A horizontal or near horizontal opening in soil excavated to a predesigned geometry by tunneling methods exclusive of cut-and-cover methods.

12.3—NOTATION

A	=	wall area (in. ² /ft) (12.7.2.3)
A_{eff}	=	effective wall area (in. ² /in.) (12.12.3.10.1b)
A_g	=	gross wall area within a length of one period (in. ² /in.); area of fiber-reinforced pipe wall per unit length of pipe (12.12.3.5) (12.12.3.10.1b) (12.15.6.3)
A_L	=	axle load, taken as 50 percent of all axle loads that can be placed on the structure at one time (kip); sum of all axle loads in an axle group (kip); total axle load on single axle or tandem axles (kip) (12.8.4.2) (12.9.4.2) (12.9.4.5)
A_s	=	tension reinforcement area on cross-section width, b (in. ² /ft) (12.10.4.2.4a) (12.10.4.2.4b) (C12.11.4)
A_{smax}	=	minimum flexural reinforcement area without stirrups (in. ² /ft) (12.10.4.2.4c)
A_T	=	area of the top portion of the structure above the springline (ft ²) (12.8.4.2)
A_{vr}	=	stirrup reinforcement area to resist radial tension forces on cross-section width, b , in each line of stirrups at circumferential spacing, s_v (in. ² /ft) (12.10.4.2.6)
A_{vs}	=	required area of stirrups for shear reinforcement (in. ² /ft) (12.10.4.2.6)
B	=	width of culvert (ft) (C12.6.2.2.5)
B_c	=	outside diameter or width of the structure (ft) (12.6.6.3) (12.11.2.2.1)
B'_c	=	out-to-out vertical rise of pipe (ft) (12.6.6.3)
B_d	=	horizontal width of trench at top of pipe (ft) (12.11.2.2.1)
B_{FE}	=	earth load bedding factor (12.10.4.3.1)
B_{FLL}	=	live load bedding factor (12.10.4.3.1)
B_1	=	crack control coefficient for effect of cover and spacing of reinforcement (C12.10.4.2.4d)
b	=	width of section (12.10.4.2.4a) (12.10.4.2.4c)
b_e	=	element effective width (in.) (12.12.3.10.1b)
C_A	=	constant corresponding to the shape of the pipe (12.10.4.3.2b)
C_d	=	load coefficient for trench installation (12.11.2.2)
C_{dt}	=	load coefficient for tunnel installation (12.13.2.1)
C_H	=	adjustment factor for shallow cover heights over metal box culverts (12.9.4.4)
C_L	=	width of culvert on which live load is applied parallel to span (ft); live load coefficient, as specified in Article 12.12.3.5 (12.7.2.2) (12.12.2.2)
C_n	=	calibration factor to account for nonlinear effects (12.12.3.10.1e)
C_N	=	parameter that is a function of the vertical load and vertical reaction (12.10.4.3.2b)
C_n	=	scalar calibration factor to account for some nonlinear effects (12.8.9.6)
C_S	=	steel tunnel liner plate construction stiffness (12.13.3.5)
C_s	=	construction stiffness for tunnel liner plate (kip/in.) (12.5.6.4)
C_1	=	1.0 for single axles and $0.5 + S/50 \leq 1.0$ for tandem axles; adjustment coefficient for number of axles; crack control coefficient for various types of reinforcement (12.9.4.2) (C12.10.4.2.4d)
c	=	the larger of the distance from neutral axis of profile to the extreme innermost or outermost fiber (in.) (12.12.3.10.2b)
D	=	straight leg length of haunch (in.); pipe diameter (in.); required D-load capacity of reinforced concrete pipe (klf); diameter to centroid of pipe wall (in.) (C12.6.7) (12.9.4.1) (12.12.2.2)
$D\text{-load}$	=	resistance of pipe from three-edge bearing test load to produce a 0.01-in. crack (klf) (12.10.4.3.1)
D_f	=	shape factor (12.12.3.10.2b)
D_L	=	deflection lag factor (12.12.2.2)
D_o	=	outside diameter of pipe (in.) (12.10.2.1) (12.12.2.2)
d	=	required envelope width adjacent to the structure (ft); distance from compression face to centroid of tension reinforcement (in.) (12.8.5.3) (12.10.4.2.4a) (C12.11.4)
d'	=	width of warped embankment fill to provide adequate support for skewed installation (ft) (C12.6.8.2)
d_1	=	distance from the structure (ft) (12.8.5.3)
E	=	modulus of elasticity of the plastic (ksi); initial modulus of elasticity (ksi) (12.12.3.3) (12.12.3.6)
E_{cf}	=	circumferential flexural modulus (ksi) (12.15.3.1) (12.15.5.2)
E_m	=	modulus of elasticity of metal (ksi) (12.7.2.4)
E_p	=	short- or long-term modulus of pipe material, as specified in Table 12.12.3.3-1 (ksi) (12.12.2.2) (12.8.9.6)
$E(x)$	=	lateral unbalanced distributed load on culvert below sloping ground and skewed at end wall (lbs.) (C12.6.2.2.5)

F	= concentrated load acting at the crown of a culvert (kip) (C12.6.2.2.5)
F_c	= curvature correction factor (12.10.4.2.5)
F_{cr}	= factor for adjusting crack control relative to average maximum crack width of 0.01 in. corresponding to $F_{cr} = 1.0$ (12.10.4.2.4d)
F_d	= factor for crack depth effect resulting in increase in diagonal tension, shear, and strength with decreasing d (12.10.4.2.5)
F_e	= soil-structure interaction factor for embankment installations (12.10.2.1)
FF	= flexibility factor (in./kip) (12.5.6.3) (12.7.2.6) (12.12.3.6)
F_n	= coefficient for effect of thrust on shear strength (12.10.4.2.5)
F_{rp}	= factor for process and local materials affecting radial tension strength of pipe (12.10.4.2.3)
F_{rt}	= factor for pipe size effect on radial tension strength (12.10.4.2.4c)
F_t	= soil-structure interaction factor for trench installations (12.11.2.2.1)
F_u	= specified minimum tensile strength (ksi); material yield strength for design load duration (ksi) (12.7.2.4) (12.12.3.10.1b)
F_{vp}	= process and material factors for shear strength for design of plant-made reinforced concrete pipe (12.10.4.2.3)
F_y	= yield strength of metal (ksi) (12.7.2.3)
f'_c	= compressive strength of concrete (ksi) (12.4.2.2) (12.10.4.2.4c)
f_{cr}	= critical buckling stress (ksi) (12.7.2.4)
f_s	= maximum stress in reinforcing steel at service limit state (ksi) (C12.11.4)
f_y	= specified yield point for reinforcing steel (ksi) (12.10.4.2.4a)
H	= rise of culvert (ft); height of cover from the box culvert rise to top of pavement (ft); height of cover over crown (ft); height of fill over top of pipe or culvert (ft) (C12.6.2.2.5) (12.9.4.2) (12.9.4.4) (12.9.4.5) (12.10.2.1) (12.12.3.7) (12.15.6.3)
HAF	= horizontal arching factor (C12.10.2.1)
H_D	= vertical distance from mid-height of corrugation to top grade (12.8.9.4)
H_{design}	= design height of cover above top of culvert or above crown of arches or pipes (ft) (C12.6.2.2.5)
H_L	= headwall strip reaction (kip) (C12.6.2.2.5)
H_{min}	= Minimum allowable cover dimension (C12.6.6.3)
H_w	= height of water table above springline of pipe (ft); height of water over top of pipe (ft) (12.12.3.7) (12.15.6.3)
H_1	= height of crown of culvert below ground surfaces (ft); height of cover above the footing to traffic surface (ft) (C12.6.2.2.5) (12.8.4.2)
H_2	= actual height of cover above top of culvert or above crown of arches or pipes (ft); height of cover from the structure springline to traffic surface (ft) (C12.6.2.2.5) (12.8.4.2)
h	= vertical distance from the top of cover for design height to point of horizontal load application (ft); wall thickness of pipe or box culvert (in.); height of ground surface above top of pipe (ft) (C12.6.2.2.5) (12.10.4.2.4a) (C12.11.4)
I	= moment of inertia (in. ⁴ /in.) (12.7.2.6) (12.13.3.5)
ID	= inside diameter (in.) (12.6.6.3)
I_p	= moment of inertia of pipe profile per unit length of pipe (in. ⁴); moment of inertia of the fiber-reinforced pipe wall per unit length (in. ⁴ /in.) (12.8.9.6) (12.12.2.2) (12.15.5.2)
i	= coefficient for effect of axial force at service limit state, f_s (12.10.4.2.4d) (C12.11.4)
j	= coefficient for moment arm at service limit state, f_s (12.10.4.2.4d) (C12.11.4)
K_1	= adjustment factor for span and depth of fill (12.9.4.2)
K_2	= adjustment factor for depth of fill (12.9.4.2)
K_b	= bedding coefficient (12.12.2.2)
K_h	= lateral earth pressure for culvert under sloping ground (psf/lf) (C12.6.2.2.5)
K_{h1}	= lateral earth pressure distribution acting on upslope surface of culvert (psf/lf) (C12.6.2.2.5)
K_{h2}	= lateral earth pressure distribution acting on downslope surface of culvert (psf/lf) (C12.6.2.2.5)
K_t	= time factor (12.12.3.10.1b)
K_{wa}	= factor for uncertainty in level of ground water table (12.12.3.8) (C12.12.3.8)
K_{yE}	= installation factor (12.12.3.5)
k	= soil stiffness factor; plate buckling coefficient; edge support coefficient (12.7.2.4) (12.12.3.10.1b) (C12.13.3.3)
L	= distance along length of culvert from expansion joint to the centerline of the headwall (ft); length of stiffening rib on leg (in.) (C12.6.2.2.5) (12.9.4.1)
$LLDF$	= live load distribution factor, as specified in Article 3.6.1.2.6 (12.7.2.2)
L_w	= lane width (ft) (12.8.4.2)

ℓ_d	=	development length (12.10.4.4.3)
ℓ_{db}	=	basic development length of welded deformed wire reinforcement (in) (12.10.4.4.4)
ℓ_w	=	live load patch length at depth H , as specified in Article 3.6.1.2.6a; horizontal live load distribution width in the circumferential direction, at the elevation of the crown (in.) (12.7.2.2) (12.12.3.5)
M_{dl}	=	dead load moment (kip-ft/ft); sum of the nominal crown and haunch dead load moments (kip-ft/ft) (12.9.4.2)
M_{dlu}	=	factored dead load moment, as specified in Article 12.9.4.2 (kip-ft) (12.9.4.3)
M_{ll}	=	live load moment (kip-ft/ft); sum of the nominal crown and haunch live load moments (kip-ft/ft) (12.9.4.2)
M_{llu}	=	factored live load moment, as specified in Article 12.9.4.2 (kip-ft) (12.9.4.3)
M_n	=	factored moment resistance (12.8.9.5)
M_{nu}	=	factored moment acting on cross-section width, b , as modified for effects of compressive or tensile thrust (kip-in./ft) (12.10.4.2.6)
M_p	=	plastic moment capacity of section (12.8.9.5)
M_{pc}	=	crown plastic moment capacity (kip-ft/ft) (12.9.4.3)
M_{ph}	=	haunch plastic moment capacity (kip-ft/ft) (12.9.4.3)
M_s	=	flexural moment at service limit state (kip-in./ft); moment acting on a cross-section of width, b , at service limit state taken as an absolute value in design equations (kip-in./ft); secant constrained soil modulus as specified in Table 12.12.3.5-1 or Table 12.12.3.5-3 (ksi) (12.8.9.6) (12.10.4.2.4d) (C12.11.4) (12.12.2.2) (12.12.3.5)
M_{thick}	=	adjusted moment (12.10.4.2.2)
M_{thin}	=	moment calculated using thin ring theory (12.10.4.2.2)
M_u	=	factored applied moment; ultimate moment acting on cross-section width, b (kip-in./ft) (12.8.9.5) (12.10.4.2.4a)
N_s	=	axial thrust acting on a cross-section width, b , at service limit state taken as positive when compressive and negative when tensile (kip/ft) (12.10.4.2.4d) (C12.11.4)
N_u	=	axial thrust acting on cross-section width, b , at strength limit state (kip/ft) (12.10.4.2.4a)
n	=	number of adjoining traffic lanes (12.8.4.2)
P_{Brg}	=	allowable bearing pressure to limit compressive strain in the trench wall or embankment (ksf) (12.8.5.3)
P_c	=	proportion of total moment carried by crown of metal box culvert (12.9.4.3)
P_{FD}	=	factored dead load vertical crown pressure as specified in Article 12.12.3.4, with VAF taken as 1.0 and D_o taken as S (ksf) (12.7.2.2)
P_{FL}	=	factored live load vertical crown pressure, as specified in Article 12.12.3.4 (ksf) (12.7.2.2)
P_L	=	live load pressure, as specified in Article 3.6.1.2.6 (psi) (12.12.2.2) (12.15.5.2)
P_{sp}	=	soil prism pressure evaluated at pipe springline as specified in Article 12.12.3.7 (psi); soil prism pressure, EV , evaluated at the top of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi) (12.12.2.2) (12.15.5.2)
P_{st}	=	stub compression capacity from AASHTO T 341 (lb/in.) (12.12.3.10.1b)
P_w	=	hydrostatic water pressure (psi) (12.12.3.8)
P_1	=	horizontal pressure from the structure at a distance, d_1 (ksf) (12.8.5.3)
p	=	positive projection ratio (12.10.4.3.2b)
q	=	ratio of the total lateral pressure to the total vertical pressure (12.10.4.3.2a)
R	=	rise of structure (ft); rise of box culvert or long-span structural plate structures (ft); average radius of the concrete pipe; radius to centroid of pipe wall profile (in.) (12.8.4.1) (12.9.4.1) (12.9.4.5) (12.10.4.2.2)
R_{AL}	=	axle load correction factor (12.9.4.6)
R_b	=	nominal axial force in culvert wall to cause general buckling (12.8.9.6)
R_c	=	corner radius of the structure (ft); concrete strength correction factor (12.8.5.3) (12.9.4.6)
R_f	=	factor related to required relieving slab thickness, applicable for box structures where the span is less than 26.0 ft (12.9.4.6)
R_H	=	horizontal footing reaction component (kip/ft) (12.8.4.2) (12.9.4.3)
R_h	=	haunch moment reduction factor; correction factor for backfill soil geometry (12.8.9.6) (12.12.3.10.1e)
R_n	=	nominal resistance (klf) (12.5.1)
R_r	=	factored resistance (klf); factored resistance to thrust (kip/ft) (12.5.1)
R_T	=	top arc radius of long-span structural plate structures (ft) (12.8.3.2)
R_t	=	factored thrust resistance (12.8.9.5)
R_V	=	vertical footing reaction component (kip/ft) (12.8.4.2)
R_w	=	water buoyancy factor (12.15.6.3)
R_ϕ	=	(ϕ_r/ϕ_f) ; ratio of resistance factors for radial tension and moment specified in Article 12.5.5 (12.10.4.2.4c)
r	=	radius of gyration (in.); radius to centerline of concrete pipe wall (in.) (12.7.2.4) (12.10.4.2.5)
r_c	=	radius of crown (ft) (12.9.4.1)

r_h	=	radius of haunch (ft) (12.9.4.1)
r_s	=	radius of the inside reinforcement (in.) (12.10.4.2.4c)
S	=	pipe, tunnel, or box diameter or span (in. or ft as indicated); culvert span (ft); span of structure between springlines of long-span structural plate structures (ft); box culvert span (ft) (12.6.6.3) (C12.6.7) (12.7.2.2) (12.7.2.4) (12.8.4.1) (12.8.4.2) (12.8.9.6) (12.9.4.1) (12.9.4.2) (12.9.4.5) (12.12.3.6)
S_b	=	long-term ring-bending strain (in./in.) (12.15.3.2)
S_H	=	hoop stiffness factor (12.12.3.5)
S_i	=	internal diameter or horizontal span of the pipe (in.) (12.10.4.2.4b)
S_ℓ	=	spacing of circumferential reinforcement (in.) (12.10.4.2.4d)
S_1, S_2	=	shear forces acting along culvert bearing lines (lbs.) (C12.6.2.2.5)
s_v	=	spacing of stirrups (in.) (12.10.4.2.6)
T	=	total dead load and live load thrust in the structure (kip/ft) (12.8.5.3)
T_f	=	factored thrust (12.8.9.5)
T_L	=	factored thrust per unit length (kip/ft) (12.7.2.2)
T_s	=	service thrust per unit length (lb/in.) (12.12.3.5)
T_u	=	factored thrust per unit length (lb/in.) (12.12.3.5)
t	=	required thickness of cement concrete relieving slab (in.); thickness of element (in.) (12.9.4.6) (12.10.4.2.2) (12.12.3.10.1b)
t_b	=	basic thickness of cement concrete relieving slab (in.); clear cover over reinforcement (in.) (12.9.4.6) (12.10.4.2.4d)
V	=	unfactored footing reaction (kip/ft) (12.9.4.5)
VAF	=	vertical arching factor (12.7.2.2) (12.10.2.1)
V_c	=	factored shear force acting on cross-section width, b , which produces diagonal tension failure without stirrup reinforcement (kip/ft) (12.10.4.2.6)
V_{DL}	=	$[H_2(S) - A_T] \gamma_s/2$ (kip/ft) (12.8.4.2)
V_L	=	headwall strip reaction (kip) (C12.6.2.2.5)
V_{LL}	=	$n(A_L)/(8 + 2 H_1)$ (kip/ft) (12.8.4.2)
V_n	=	nominal shear resistance of pipe section without radial stirrups per unit length of pipe (kip/ft) (12.10.4.2.5)
V_r	=	factored shear resistance per unit length (kip/ft) (12.10.4.2.5)
V_u	=	ultimate shear force acting on cross-section width, b (kip/ft) (12.10.4.2.5)
W_E	=	total unfactored earth load on pipe or liner (kip/ft) (12.10.2.1)
W_F	=	fluid load in the pipe (kip/ft) (12.10.4.3.1)
W_L	=	total unfactored live load on unit length pipe specified in Article 12.10.2.3 (kip/ft) (12.10.4.3.1)
W_T	=	total dead and live load on pipe or liner (kip/ft) (12.10.4.3.1)
w	=	unit weight of soil (pcf); total clear width of element between supporting elements (in.) (12.10.2.1) (12.12.3.10.1b)
w_t	=	tire patch width, as specified in Article 3.6.1.2.5 (in.) (12.7.2.2)
x	=	parameter which is a function of the area of the vertical projection of the pipe over which active lateral pressure is effective (12.10.4.3.2b)
α	=	skew angle between the highway centerline or tangent thereto and the culvert headwall (degrees) (C12.6.2.2.5)
β	=	angle of fill slope measured from horizontal (degrees) (C12.6.2.2.5)
γ_b	=	unit weight of buoyant soil (lb/ft ³) (12.12.3.7)
γ_{EV}	=	load factor for vertical pressure from dead load of earth fill; load factor for vertical earth pressure (12.12.3.5) (12.12.3.10.2b) (12.15.6.3)
γ_{LL}	=	load factor for live load (12.12.3.5)
γ_s	=	unit weight of backfill (kef); soil unit weight (kef); wet unit weight of soil (lb/ft ³) (12.8.4.2) (C12.9.2) (12.9.4.2) (12.9.4.5) (12.11.2.2) (12.12.3.7) (12.13.2.1)
γ_w	=	unit weight of water (lb/ft ³) (12.12.3.8) (12.15.6.3)
γ_{WA}	=	load factor for hydrostatic pressure (12.12.3.5)
Δ	=	calculated differential settlements across the structure taken from springline-to-springline; return angle of the structure (degrees); haunch radius included angle (12.8.4.1) (12.8.4.2) (12.9.4.1)
Δ_A	=	total allowable deflection of pipe (in.) (12.12.2.2) (12.15.4)
Δ_f	=	deflection of pipe due to flexure (in.) (12.12.3.10.2b)
Δ_t	=	total deflection of pipe (in.) (12.12.2.2)
ϵ_{bck}	=	nominal strain capacity for general buckling (in./in.) (12.12.3.10.1e)
ϵ_{fb}	=	factored buckling strain demand (in./in.) (12.15.6.3)
ϵ_f	=	factored strain due to flexure (in./in.) (12.12.3.10.2b)
ϵ_{sc}	=	service compressive strain, as specified in Article 12.12.3.10.1c (in./in.) (12.12.2.2)

ϵ_{uc}	=	factored compressive strain due to thrust (12.12.3.10.1c)
ϵ_{yc}	=	factored compressive strain limit, as specified in Table 12.12.3.3-1 (12.12.3.10.1b)
ϵ_{yt}	=	service long-term strain limit, as specified in Table 12.12.3.3-1 (12.12.3.10.2b)
η_{EV}	=	load modifier, specified in Article 1.3.2, as it applies to vertical earth loads on culverts (12.12.3.5)
η_{LL}	=	load modifier, specified in Article 1.3.2, as it applies to live loads on culverts (12.12.3.5)
θ	=	rotation of the structure (C12.8.4.1)
λ	=	slenderness factor (12.12.3.10.1b)
ν	=	Poisson's ratio of soil (12.12.3.10.1e)
ρ	=	effective width factor (12.10.4.2.5) (12.12.3.10.1b)
ϕ	=	resistance factor (12.5.1) (12.5.5) (12.7.2.3)
ϕ_b	=	resistance factor for general buckling (12.5.5) (12.8.9.6)
ϕ_{bck}	=	resistance factor for global buckling (12.5.5) (12.12.3.10.1e)
ϕ_f	=	resistance factor for flexure (12.5.5) (12.10.4.2.4c)
ϕ_h	=	resistance factor for plastic hinge (12.5.5)
ϕ_r	=	resistance factor for radial tension (12.5.5) (12.10.4.2.4c) (12.10.4.2.6)
ϕ_s	=	resistance factor for soil stiffness, $\phi_s = 0.9$; resistance factor for soil pressure (12.5.5) (12.8.9.6) (12.12.3.5) (12.12.3.10.1e)
ϕ_T	=	resistance factor for thrust effects (12.5.5) (12.12.3.10.1d)
Ψ	=	central angle of pipe subtended by assumed distribution of external reactive force (degrees) (12.10.4.2.1)
ω	=	spacing of corrugation (in.) (12.12.3.10.1b)

12.3.1—Abbreviations

GC:	clayey gravel
GM:	silty gravel
GP:	poorly-graded gravel
GW:	well-graded gravel
PE:	polyethylene
PL:	prism load
PP:	polypropylene
PVC:	polyvinyl chloride
SC:	clayey sand
SM:	silty sand
SP:	poorly-graded sand
SW:	well-graded sand

12.4—SOIL AND MATERIAL PROPERTIES

12.4.1—Determination of Soil Properties

12.4.1.1—General

Subsurface exploration shall be carried out to determine the presence and influence of geologic and environmental conditions that may affect the performance of buried structures. For buried structures supported on footings and for pipe arches and large diameter pipes, a foundation investigation should be conducted to evaluate the capacity of foundation materials to resist the applied loads and to satisfy the movement requirements of the structure.

C12.4.1.1

The following information may be useful for design:

- Strength and compressibility of foundation materials;
- Chemical characteristics of soil and surface waters, e.g., pH, resistivity, and chloride content of soil and pH, resistivity, and sulfate content of surface water;
- Stream hydrology, e.g., flow rate and velocity, maximum width, allowable headwater depth, and scour potential; and
- Performance and condition survey of culverts in the vicinity.

12.4.2—Materials**12.4.2.1—Aluminum Pipe and Structural Plate Structures**

Aluminum for corrugated metal pipe and pipe-arches shall comply with the requirements of AASHTO M 196 (ASTM B745). Aluminum for structural plate pipe, pipe-arch, arch, and box structures shall meet the requirements of AASHTO M 219 (ASTM B746).

12.4.2.2—Concrete

Concrete shall conform to Article 5.4, except that f'_c may be based on cores.

12.4.2.3—Precast Concrete Pipe

Precast concrete pipe shall comply with the requirements of AASHTO M 170M and M 170 (ASTM C76M and C76), M 242M/M 242 (ASTM C655M and C655), or ASTM C1765. Design wall thickness other than the standard wall dimensions may be used, provided that the design complies with all applicable requirements of this Section.

12.4.2.4—Precast Concrete Structures

Precast concrete arch, elliptical, and box structures shall comply with the requirements of AASHTO M 206M/M 206 (ASTM C506M and C506), M 207M/M 207 (ASTM C507M and C507), M 259 (ASTM C789), and M 273 (ASTM C850).

12.4.2.5—Steel Pipe and Structural Plate Structures

Steel for corrugated metal pipe and pipe-arches shall comply with the requirements of AASHTO M 36 (ASTM A760/A760M). Steel for structural plate pipe, pipe-arch, arch, and box structures shall meet the requirements of AASHTO M 167M/M 167 (ASTM A761/A761M).

12.4.2.6—Deep Corrugated Structures

Steel for deep corrugated structural plate shall comply with the requirements of AASHTO M 167M/M 167. Deep corrugated structural plate may be reinforced.

C12.4.2.6

Reinforcement for deep corrugated structures may consist of structural shapes, or deep corrugated structural plate meeting the requirements of AASHTO M 167M/M 167, with or without nonshrink grout, complete with shear studs.

12.4.2.7—Steel Reinforcement

Reinforcement shall comply with the requirements of Article 5.4.3, and shall conform to one of the following: AASHTO M 31M/M 31 (ASTM A615/A615M), M 32M/M 32, M 55M/M 55, M 221M/M 221,

M 336M/M 336, ASTM A1064/A1064M, or ASTM A706/A706M.

The nominal yield strength shall be the minimum as specified for the grade of steel selected, but shall not exceed 80 ksi.

12.4.2.8—Thermoplastic Pipe

Plastic pipe may be solid wall, corrugated, or profile wall and may be manufactured of polyethylene (PE) or polyvinyl chloride (PVC).

PE pipe shall comply with the requirements of ASTM F714 for solid wall pipe, AASHTO M 294 for corrugated pipe, and ASTM F894 for profile wall pipe.

PVC pipe shall comply with the requirements of AASHTO M 278 for solid wall pipe, ASTM F679 for solid wall pipe, and AASHTO M 304 for profile wall pipe.

12.4.2.9—Fiberglass Pipe

Glass-fiber-reinforced (fiberglass) pipe shall be solid wall and manufactured from glass-fiber-reinforced thermosetting resins, with or without aggregates or liners, and shall comply with the requirements of ASTM D3262. For pipe exposed to sunlight after installation, in addition to the requirements of ASTM D3262, the liner and surface layers shall provide protection from ultraviolet exposure for the design life of the product.

12.4.2.10—Steel-Reinforced Thermoplastic Culverts

Steel-reinforced thermoplastic (SRPE) culverts have a profile wall which may be ribbed or corrugated. Ribbed profile wall steel-reinforced thermoplastic culverts shall meet the requirements of AASHTO M 335 and MP 40 for larger diameters (66.0 to 120 in.). Corrugated profile wall steel-reinforced thermoplastic culverts shall meet requirements of AASHTO MP 40.

12.5—LIMIT STATES AND RESISTANCE FACTORS

12.5.1—General

Buried structures and their foundations shall be designed by the appropriate methods specified in Articles 12.7 through 12.15 to resist the load combinations specified in Articles 12.5.2 and 12.5.3.

The factored resistance, R_r , shall be calculated for each applicable limit state as:

$$R_r = \phi R_n \quad (12.5.1-1)$$

where:

R_n = the nominal resistance
 ϕ = the resistance factor, specified in Table 12.5.5-1

C12.4.2.9

ASTM D3262 specifies pipe for use in conveyance of sanitary sewer, storm water, and some industrial waste, primarily in buried applications. The standard includes pipes with stiffness from 9 to 72 psi. The lowest pipe stiffness allowed, 9 psi, should only be used for specific applications (e.g., concrete encasement), where the pipe is not subjected to typical installation forces such as backfill compaction.

C12.5.1

Procedures for determining nominal resistance are provided in Articles 12.7 through 12.15 for:

- Metal pipe, pipe arches, and arch structures;
- Long-span and deep corrugated structural plate structures;
- Structural plate box structures;
- Reinforced precast concrete pipe;
- Reinforced concrete cast-in-place and precast box structures and reinforced cast-in-place arches;
- Thermoplastic pipe;
- Steel tunnel liner plate;
- Precast reinforced concrete three-sided structures;

- Fiberglass pipe; and
- Steel-reinforced thermoplastic culverts.

12.5.2—Service Limit State

Buried structures shall be investigated at Service Load Combination I, as specified in Table 3.4.1-1.

- Deflection of metal structures, tunnel liner plate, thermoplastic pipe, and fiberglass pipe, and
- Crack width in reinforced concrete structures.

12.5.3—Strength Limit State

Buried structures and tunnel liners shall be investigated for construction loads and at Strength Load Combinations I and II, as specified in Table 3.4.1-1, as follows:

- For metal structures:
 - Wall area
 - Buckling
 - Seam failure
 - Flexibility limit for construction
 - Flexure of box and deep corrugated structures only
- For concrete structures:
 - Flexure
 - Shear
 - Thrust
 - Radial tension
- For thermoplastic pipe:
 - Wall area
 - Buckling
 - Flexibility limit
- For tunnel liner plate:
 - Wall area
 - Buckling
 - Seam strength
 - Construction stiffness
- For fiberglass pipe:
 - Flexure
 - Buckling
 - Flexibility limit
- For steel-reinforced thermoplastic culverts:
 - Wall area
 - Buckling
 - Flexibility limit for construction

C12.5.2

Deflection of a tunnel liner depends significantly on the amount of over-excavation of the bore and is affected by delay in backpacking or inadequate backpacking. The magnitude of deflection is not primarily a function of soil modulus or the liner plate properties, so it cannot be computed with usual deflection formulas.

Where the tunnel clearances are important, the designer should oversize the structure to allow for deflection.

C12.5.3

Strength Load Combinations III and IV and the extreme event limit state do not control due to the relative magnitude of loads applicable to buried structures as indicated in Article 12.6.1. Buried structures have been shown not to be controlled by fatigue.

Flexibility limit requirement is waived for some metal structures. See design provisions in Article 12.8.

Thermoplastic pipe has many profile wall geometries and some of these are made up of thin sections that may be limited based on local buckling. The strength limit state for wall area includes evaluating the section capacity for local buckling.

Steel-reinforced thermoplastic culverts are comprised of thin sections that may be limited due to local buckling. The strength limit state for wall area includes evaluating the section capacity for local buckling.

12.5.4—Load Modifiers and Load Factors

Load modifiers shall be applied to buried structures and tunnel liners as specified in Article 1.3, except that the load modifiers for construction loads shall be taken as 1.0. For strength limit states, buried structures shall be considered redundant. Operational classification shall be determined on the basis of continued function and/or safety of the roadway.

12.5.5—Resistance Factors

Resistance factors for buried structures shall be taken as specified in Table 12.5.5-1. Values of resistance factors for the geotechnical design of foundations for buried structures shall be taken as specified in Section 10.

C12.5.5

The standard installations for direct design of concrete pipe were developed based on extensive parameter studies using the soil-structure interaction program, SPIDA. Although past research validates that SPIDA soil-structure models correlate well with field measurements, variability in culvert installation methods and materials suggests that the design for Type I installations be modified. This revision reduces soil-structure interaction for Type I installations by ten percent until additional performance documentation on installation in the field is obtained.

The new thermoplastic design method evaluates more load conditions than prior specifications. Separate resistance factors are provided for each mode of behavior. The resistance factor for buckling is set at 0.7 and preserves the same level of safety as prior editions of these Specifications with the inclusion of the installation factor of Article 12.12.3.5. Buckling is an undesirable failure mode for culverts. Buckling can result in near total collapse of the culvert and blockage of the waterway.

Table 12.5.5-1—Resistance Factors for Buried Structures

Structure Type	Resistance Factor
Metal Pipe, Arch, and Pipe Arch Structures	
Helical pipe with lock seam or fully welded seam:	
• Minimum wall area and buckling	1.00
Annular pipe with spot-welded, riveted, or bolted seam:	
• Minimum wall area and buckling	1.00
• Minimum longitudinal seam strength	0.67
• Bearing resistance to pipe arch foundations	Refer to Section 10
Structural plate pipe:	
• Minimum wall area and buckling	1.00
• Minimum longitudinal seam strength	0.67
• Bearing resistance to pipe arch foundations	Refer to Section 10
Long-Span Structural Plate and Tunnel Liner Plate Structures	
• Minimum wall area	0.67
• Minimum seam strength	0.67
• Bearing resistance of pipe arch foundations	Refer to Section 10
Structural Plate Box Structures	
• Plastic moment strength	1.00
• Bearing resistance of pipe arch foundations	Refer to Section 10
Reinforced Concrete Pipe	
Direct design method:	
Type 1 installation:	0.90
• Flexure	0.82
• Shear	0.82
• Radial tension	
Other type installations:	1.00
• Flexure	0.90
• Shear	0.90
• Radial tension	0.90
Reinforced Concrete Cast-in-Place Box Structures	
• Flexure	0.90
• Shear	0.85
Reinforced Concrete Precast Box Structures	
• Flexure	1.00
• Shear	0.90
Reinforced Concrete Precast Three-Sided Structures	
• Flexure	0.95
• Shear	0.90
Thermoplastic Pipe	
PE and PVC pipe:	
• Thrust, ϕ_T	1.00
• Soil stiffness, ϕ_s	0.90
• Global buckling, ϕ_{bck}	0.70
• Flexure, ϕ_f	1.00
Fiberglass Pipe	
• Flexure, ϕ_f	0.9
• Global Buckling, ϕ_{bck}	0.63
Deep Corrugated Structural Plate Structures	
• Minimum wall area and general buckling, ϕ_b	0.70

• Minimum wall area and buckling	1.00

12.5.6—Flexibility Limits and Construction Stiffness**12.5.6.1—Corrugated Metal Pipe and Structural Plate Structures****C12.5.6.1**

Flexibility factors for corrugated metal pipe, structural plate structures, and steel-reinforced thermoplastic culverts shall not exceed the values specified in Table 12.5.6.1-1.

Limits on construction stiffness and plate flexibility are construction requirements that do not represent any limit state in service.

Table 12.5.6.1-1—Flexibility Factor Limit

Type of Construction Material	Corrugation Size (in.)	Flexibility Factor (in./kip)
Steel Pipe	0.25	43
	0.5	43
	1.0	33
Aluminum Pipe	0.25 and 0.50	
	0.060 Material Thk.	31
	0.075 Material Thk.	61
	All Others	92
Steel Plate	1.0	60
	6.0 × 2.0	
	Pipe	20
	Pipe-Arch	30
Aluminum Plate	Arch	30
	9.0 × 2.5	
	Pipe	25
	Pipe-Arch	36
Steel-Reinforced Thermoplastic Pipe	Arch	36
		68

12.5.6.2—Spiral Rib Metal Pipe and Pipe Arches

Flexibility factors for spiral rib metal pipe and pipe arches shall not exceed the values, specified in Table 12.5.6.2-1, for embankment installations conforming to the provisions of Articles 12.6.6.2 and 12.6.6.3 and for trench installations conforming to the provisions of Articles 12.6.6.1 and 12.6.6.3.

Table 12.5.6.2-1—Flexibility Factor Limits

Material	Condition	Corrugation Size (in.)	Flexibility Factor (in./kip)
Steel	Embankment	0.75 × 0.75 × 7.5	217I ^{1/3}
		0.75 × 1.0 × 11.5	140I ^{1/3}
	Trench	0.75 × 0.75 × 7.5	263I ^{1/3}
		0.75 × 1.0 × 11.5	163I ^{1/3}
Aluminum	Embankment	0.75 × 0.75 × 7.5	340I ^{1/3}
		0.75 × 1.0 × 11.5	175I ^{1/3}
	Trench	0.75 × 0.75 × 7.5	420I ^{1/3}
		0.75 × 1.0 × 11.5	215I ^{1/3}

Values of inertia, I , for steel and aluminum pipes and pipe arches shall be taken as tabulated in Tables A12-2 and A12-5.

12.5.6.3—Thermoplastic and Fiberglass Pipe

Flexibility factor, FF , of thermoplastic and fiberglass pipe shall not exceed 95.0 in./kip.

12.5.6.4—Steel Tunnel Liner Plate

Construction stiffness, C_s , in kip/in., shall not be less than the following:

- Two-flange liner plate
 $C_s \geq 0.050$ (kip/in.)
- Four-flange liner plate
 $C_s \geq 0.111$ (kip/in.)

12.6—GENERAL DESIGN FEATURES

12.6.1—Loading

Buried structures shall be designed for force effects resulting from horizontal and vertical earth pressure, pavement load, live load, and vehicular dynamic load allowance. Earth surcharge, live load surcharge, drag loads, and external hydrostatic pressure shall be evaluated where construction or site conditions warrant. Water buoyancy loads shall be evaluated for buried structures with inverts below the water table to control flotation, as indicated in Article 3.7.2. Earthquake loads should be considered only where buried structures cross active faults.

For vertical earth pressure, the maximum load factor from Table 3.4.1-2 shall apply.

Wheel loads shall be distributed through earth fills according to the provisions of Article 3.6.1.2.6.

C12.5.6.3

PE and PVC are thermoplastic materials that exhibit higher flexibility factors at high temperatures and lower flexibility factors at low temperatures. The specified flexibility factor limits are defined in relation to pipe stiffness values in accordance with ASTM D2412 at 73.4 degrees F.

C12.5.6.4

Assembled liner using two- and four-flange liner plates does not provide the same construction stiffness as a full steel ring with equal stiffness.

C12.6.1

Buried structures benefit from both earth shelter and support that reduce or eliminate from concern many of the loads and load combinations of Article 3.4. Wind, temperature, vehicle braking, and centrifugal forces typically have little effect due to earth protection. Structure dead load, pedestrian live load, and ice loads are insignificant in comparison with force effects due to earth fill loading. External hydrostatic pressure, if present, can add significantly to the total thrust in a buried pipe.

Vehicular collision forces are applicable to appurtenances such as headwalls and railings only. Water, other than buoyancy and vessel collision loads, can act only in the noncritical longitudinal direction of the culvert.

Due to the absence or low magnitude of these loadings, Service Load Combination I, Strength Load Combinations I and II, or construction loads control the design.

The finite element analyses used in the preparation of these metal box structure provisions are based on conservative soil properties of low-plasticity clay, CL , compacted to 90 percent density as specified in AASHTO T 99. Although low plasticity clay is not considered an acceptable backfill material, as indicated in Article 12.4.1.3, the FEM results have been shown to yield conservative, upper-bound moments.

The loading conditions that cause the maximum flexural moment and thrust are not necessarily the same, nor are they necessarily the conditions that will exist at the final configuration.

12.6.2—Service Limit State

12.6.2.1—Tolerable Movement

Tolerable movement criteria for buried structures shall be developed based on the function and type of structure, anticipated service life, and consequences of unacceptable movements.

12.6.2.2—Settlement

12.6.2.2.1—General

Settlement shall be determined as specified in Article 10.6.2. Consideration shall be given to potential movements resulting from:

- Longitudinal differential settlement along the length of the pipe,
- Differential settlement between the pipe and backfill, and
- Settlement of footings and unbalanced loading of skewed structures extending through embankment slopes.

12.6.2.2.2—Longitudinal Differential Settlement

Differential settlement along the length of buried structures shall be determined in accordance with Article 10.6.2.4. Pipes and culverts subjected to longitudinal differential settlements shall be fitted with positive joints to resist disjoining forces meeting the requirements of Sections 26 and 27 of the *AASHTO LRFD Bridge Construction Specifications*.

Camber may be specified for an installation to ensure hydraulic flow during the service life of the structure.

12.6.2.2.3—Differential Settlement between Structure and Backfill

C12.6.2.2.3

Where differential settlement of arch structures is expected between the structure and the side fill, the foundation should be designed to settle with respect to the backfill.

The purpose of this provision is to minimize drag loads.

Pipes with inverts shall not be placed on foundations that will settle much less than the adjacent side fill, and a uniform bedding of loosely compacted granular material should be provided.

12.6.2.2.4—Footing Settlement

C12.6.2.2.4

Footings shall be designed to provide uniform longitudinal and transverse settlement. The settlement of footings shall be large enough to provide protection

Metal pipe arch structures, long-span arch structures, and box culvert structures should not be supported on foundation materials that are relatively

against possible drag loads caused by settlement of adjacent fill. If poor foundation materials are encountered, consideration shall be given to excavation of all or some of the unacceptable material and its replacement with compacted acceptable material.

Footing design shall comply with the provisions of Article 10.6.

Footing reactions for metal box culvert structures shall be determined as specified in Article 12.9.4.5.

The effects of footing depth shall be considered in the design of arch footings. Footing reactions shall be taken as acting tangential to the arch at the point of connection to the footing and to be equal to the thrust in the arch at the footing.

12.6.2.2.5—Unbalanced Loading

Buried structures skewed to the roadway alignment and extending through an embankment fill shall be designed in consideration of the influence of unsymmetrical loading on the structure section.

unyielding compared with the adjacent sidefill. The use of massive footings or piles to prevent settlement of such structures is not recommended.

In general, provisions to accommodate uniform settlement between the footings are desirable, provided that the resulting total settlement is not detrimental to the function of the structure.

C12.6.2.2.5

Disregard of the effect of lateral unbalanced forces in the headwall design can result in failure of the headwall and adjacent culvert sections.

Due to the complexity of determining the actual load distribution on a structure subjected to unbalanced loading, the problem can be modeled using numerical methods or the following approximate method. The approximate method consists of analyzing 1.0-ft wide culvert strips for the unbalanced soil pressures wherein the strips are limited by planes perpendicular to the culvert centerline. Refer to Figure C12.6.2.2.5-1 for this method of analysis for derivation of force F . For semicomplete culvert strips, the strips may be assumed to be supported as shown in the lower part of the plan. The headwall shall be designed as a frame carrying the strip reactions, V_L and $H_L \cos \alpha$, in addition to the concentrated force, F , assumed to be acting on the crown. Force F is determined using the equations given herein.

Figure C12.6.2.2.5-1—Forces on Culvert—Approximate Analysis

The unbalanced distributed load may be estimated by the following relationships:

$$E(x) = (P_{11} - P_{21}) + \frac{2}{3}(P_{12} - P_{22}) + \frac{1}{3}(P_{13} - P_{23}) \quad (\text{C12.6.2.2.5-1})$$

Figure C12.6.2.2.5-2—Lateral Earth Pressure as a Function of Ground Slope

12.6.2.3—Uplift

Uplift shall be considered where structures are installed below the highest anticipated groundwater level.

C12.6.2.3

To satisfy this provision, the dead load on the crown of the structure should exceed the buoyancy of the culvert, using load factors as appropriate.

12.6.3—Safety Against Soil Failure**12.6.3.1—Bearing Resistance and Stability**

Pipe structures and footings for buried structures shall be investigated for bearing capacity failure and erosion of soil backfill by hydraulic gradients.

12.6.3.2—Corner Backfill for Metal Pipe Arches

The corner backfill for metal pipe arches shall be designed to account for corner pressure taken as the arch thrust divided by the radius of the pipe-arch corner. The soil envelope around the corners of pipe arches shall resist this pressure. Placement of select structural backfill compacted to unit weights higher than normal may be specified.

12.6.4—Hydraulic Design

Design criteria as specified in Article 2.6 and in the *AASHTO Drainage Manual* (2014) shall apply.

12.6.5—Scour

Buried structures shall be designed so that no movement of any part of the structure will occur as a result of scour.

In areas where scour is a concern, the wingwalls shall be extended far enough from the structure to protect the structural portion of the soil envelope surrounding the structure. For structures placed over erodible deposits, a cut-off wall or scour curtain, extending below the maximum anticipated depth of scour or a paved invert, shall be used. The footings of structures shall be placed not less than 2.0 ft below the maximum anticipated depth of scour.

12.6.6—Soil Envelope

12.6.6.1—Trench Installations

The minimum trench width shall provide sufficient space between the pipe and the trench wall to ensure sufficient working room to properly and safely place and compact backfill material.

The contract documents shall require that stability of the trench be ensured by either sloping the trench walls or providing support of steeper trench walls in conformance with OSHA or other regulatory requirements.

C12.6.6.1

As a guide, the minimum trench width should not be less than the greater of the pipe diameter plus 16.0 in. or the pipe diameter times 1.5 plus 12.0 in. The use of specially designed equipment may enable satisfactory installation and embedment even in narrower trenches. If the use of such equipment provides an installation meeting the requirements of this Article, narrower trench widths may be used as approved by the Engineer.

For trenches excavated in rock or high-bearing soils, decreased trench widths may be used up to the limits required for compaction. For these conditions, the use of a flowable backfill material, as specified in Article 12.4.1.3, allows the envelope to be decreased to within 6.0 in. along each side of the pipe.

12.6.6.2—Embankment Installations

The minimum width of the soil envelope shall be sufficient to ensure lateral restraint for the buried structure. The combined width of the soil envelope and embankment beyond shall be adequate to support all the loads on the culvert and to comply with the movement requirements specified in Article 12.6.2.

C12.6.6.2

As a guide, the minimum width of the soil envelope on each side of the buried structure should not be less than the widths specified in Table C12.6.6.2-1:

Table C12.6.6.2-1—Minimum Width of Soil Envelope

Diameter, <i>S</i> (in.)	Minimum Envelope Width (ft)
<24	<i>S</i> /12
24–144	2.0
>144	5.0

12.6.6.3—Minimum Cover

The minimum cover, including a well-compacted granular subbase and base course, shall not be less than that specified in Table 12.6.6.3-1, where:

- S = diameter of pipe (in.)
 B_c = outside diameter or width of the structure (ft)
 B'_c = out-to-out vertical rise of pipe (ft)
 ID = inside diameter (in.)

C12.6.6.3

McGrath et al. (2005) has shown that the significant thermal expansion in thermoplastic pipe can affect pavement performance under shallow fills. Depending on the pipe material and the pavement type above it, the minimum cover may include the pavement thickness and base course, along with the sub-base.

Minimum Cover Orientation

H_{min} = minimum allowable cover dimension

Note: The minimum cover dimension is not to be confused with the fill height used for calculation purposes, which shall be from the top of the pipe to the top of the surface, regardless of the pipe type or pavement type.

Figure C12.6.6.3-1—Minimum Cover Orientation

If the minimum cover provided in Table 12.6.6.3-1 is not sufficient to avoid placement of the pipe within the pavement layer, then the minimum cover should be increased to a minimum of the pavement thickness, unless an analysis is performed to determine the effect on both the pipe and the pavement.

Table 12.6.6.3-1—Minimum Cover

Type	Condition	Minimum Cover*
Corrugated Metal Pipe	—	$S/8 \geq 12.0$ in.
Spiral Rib Metal Pipe	Steel Conduit	$S/4 \geq 12.0$ in.
	Aluminum Conduit where $S \leq 48.0$ in.	$S/2 \geq 12.0$ in.
	Aluminum Conduit where $S > 48.0$ in.	$S/2.75 \geq 24.0$ in.
Structural Plate Pipe Structures	—	$S/8 \geq 12.0$ in.
Long-Span Structural Plate Pipe Structures	—	Refer to Table 12.8.3.1.1-1
Structural Plate Box Structures	—	1.4 ft., as specified in Article 12.9.1
Deep Corrugated Structural Plate Structures	—	See Article 12.8.9.4
Fiberglass Pipe	—	12.0 in.
Thermoplastic Pipe	Under unpaved areas	$ID/8 \geq 12.0$ in.
	Under paved roads	$ID/2 \geq 24.0$ in.
Steel-Reinforced Thermoplastic Culverts	—	$S/5 \geq 12.0$ in.
* Minimum cover taken from top of rigid pavement or bottom of flexible pavement		
Reinforced Concrete Pipe	Under unpaved areas or top of flexible pavement	$B_d/8$ or $B'_d/8$, whichever is greater, ≥ 12.0 in.
Reinforced Concrete Pipe	Under bottom of rigid pavement	9.0 in.

If soil cover is not provided, the top of precast or cast-in-place reinforced concrete box structures shall be designed for direct application of vehicular loads.

Additional cover requirements during construction shall be taken as specified in Article 30.5.5 of the *AASHTO LRFD Bridge Construction Specifications*.

12.6.7—Minimum Spacing between Multiple Lines of Pipe

The spacing between multiple lines of pipe shall be sufficient to permit the proper placement and compaction of backfill below the haunch and between the structures.

Contract documents should require that backfilling be coordinated to minimize unbalanced loading between multiple, closely spaced structures. Backfill should be kept level over the series of structures when possible. The effects of significant roadway grades across a series of structures shall be investigated for the stability of flexible structures subjected to unbalanced loading.

C12.6.7

As a guide, the minimum spacing between pipes should not be less than that shown in Table C12.6.7-1.

Table C12.6.7-1—Minimum Pipe Spacing

Type of Structure	Minimum Distance Between Pipes (ft)
Round Pipes Diameter, D (ft)	
<2.0	1.0
2.0–6.0	$D/2$
>6.0	3.0
Pipe Arches Span, S (ft)	
<3.0	1.0
3.0–9.0	$S/3$
9.0–16.0	3.0
Arches Span, S (ft)	
All Spans	2.0

12.6.8—End Treatment

12.6.8.1—General

Protection of end slopes shall be given special consideration where backwater conditions occur or where erosion or uplift could be expected. Traffic safety treatments, such as a structurally adequate grating that conforms to the embankment slope, extension of the culvert length beyond the point of hazard, or provision of guide rail, should be considered.

12.6.8.2—Flexible Culverts Constructed on Skew

The end treatment of flexible culverts skewed to the roadway alignment and extending through embankment fill shall be warped to ensure symmetrical loading along either side of the pipe or the headwall shall be designed to support the full thrust force of the cut end.

The minimum spacing can be reduced if a flowable backfill material, as specified in Article 12.4.1.3, is placed between the structures.

C12.6.8.1

Culvert ends may represent a major traffic hazard.

When backwater conditions occur, pressure flow at the outlet end of culverts can result in uplift of pipe sections having inadequate cover and scour of erosive soils due to high velocities of water flow. Measures to control these problems include anchoring the pipe end in a concrete headwall or burying it in riprap having sufficient mass to resist uplift forces as well as lining outlet areas with riprap or concrete to prevent scour.

C12.6.8.2

For flexible structures, additional reinforcement of the end is recommended to secure the metal edges at inlet and outlet against hydraulic forces. Reinforcement methods include reinforced concrete or structural steel collars, tension tiebacks or anchors in soil, partial headwalls, and cut-off walls below invert elevation.

As a guide in Figure C12.6.8.2-1, limits are suggested for skews to embankments unless the embankment is warped. It also shows examples of warping an embankment cross-section to achieve a square-ended pipe for single and multiple flexible pipe installations where the minimum width of the warped embankment, d' , is taken as 1.50 times the sum of the rise of the culvert and the cover or three times the span of the culvert, whichever is less.

Figure C12.6.8.2-1—End Treatment of Skewed Flexible Culvert

12.6.9—Corrosive and Abrasive Conditions

The degradation of culvert material due to corrosion and abrasion is a consideration when selecting material types. The invert of culverts receives the largest impact due to corrosion and abrasion; however, the surrounding soil properties and groundwater may impact other portions of the culvert barrel.

Culvert service life is determined by the owner and is established based on the importance of the culvert. Considerations are given to the roadway classification, average daily traffic, risk of premature failure, and costs to replace.

Ensure the culvert material service life meets or exceeds the culvert service life. Use of different metals, protective linings, increased gauge thickness, or a combination of these methods are commonly used for metal culverts. Additional concrete cover over reinforcing steel or protective coatings are common approaches used in concrete culverts.

C12.6.9

Several long-term tests of the field performance of buried structures have resulted in development of empirical guidelines for estimating culvert material service life due to the effects of corrosion and abrasion. A representative listing includes Bellair and Ewing (1984), Koepf and Ryan (1986), Hurd (1984), Meacham et al. (1982), Potter (1988), Funahashi and Bushman (1991), Sagues (2001), NCHRP Synthesis No. 474 (2015), and Sargand (2016).

Commonly-used culvert service life requirements range from 25 to 75 years of service.

The National Corrugated Steel Pipe Association offers an online Service Life Calculator for corrugated steel pipe that requires input of soil resistivity, water pH, FHWA abrasion level (1–4), and a determination if the water contains soft water with CaCO_3 . FHWA abrasion levels are as follows:

- Level 1—Nonabrasive conditions exist in areas of no bed load and very low velocities. This is the condition assumed for the soil side of drainage pipes.
- Level 2—Low abrasive conditions exist in areas of minor bed loads of sand and velocities of 5.0 ft/s or less.
- Level 3—Moderate abrasive conditions exist in areas of moderate bed loads of sand and gravel and velocities between 5.0 ft/s and 15.0 ft/s.
- Level 4—Severe abrasive conditions exist in areas of heavy bed loads of sand, gravel, and rock and velocities exceeding 15.0 ft/s.

12.7—METAL PIPE, PIPE ARCH, ARCH STRUCTURES, AND STEEL-REINFORCED THERMOPLASTIC CULVERTS**12.7.1—General**

The provisions herein shall apply to the design of buried corrugated and spiral rib metal pipe and structural plate pipe structures.

Corrugated metal pipe and pipe-arches may be of riveted, welded, or lockseam fabrication with annular or helical corrugations. Structural plate pipe, pipe-arches, and arches shall be bolted with annular corrugations only.

The rise-to-span ratio of structural plate arches shall not be less than 0.3.

The provisions of Article 12.8 shall apply to structures with a radius exceeding 13.0 ft.

C12.7.1

These structures become part of a composite system comprised of the metal pipe section and the soil envelope, both of which contribute to the structural behavior of the system.

For information regarding the manufacture of structures and structural components referred to herein, AASHTO M 196 (ASTM B745) for aluminum, AASHTO M 36 (ASTM A760/A760M) for steel corrugated metal pipe and pipe-arches, and AASHTO M 167M/M 167 (ASTM A761/A761M) for steel and AASHTO M 219 (ASTM B746) for aluminum structural plate pipe may be consulted.

12.7.2—Safety Against Structural Failure

Corrugated and spiral rib metal pipe and pipe arches and structural plate pipe shall be investigated at the strength limit state for:

- wall area of pipe,
- buckling strength, and
- seam resistance for structures with longitudinal seams.

12.7.2.1—Section Properties

Dimensions and properties of pipe cross-sections; minimum seam strength; mechanical and chemical requirements for aluminum corrugated and steel corrugated pipe and pipe-arch sections; and aluminum and steel corrugated structural plate pipe, pipe-arch, and arch sections, may be taken as given in Appendix A12.

Dimensions, properties of pipe cross-sections, and material properties for steel-reinforced thermoplastic culverts shall be provided by the pipe manufacturer.

C12.7.2.1

Steel-reinforced thermoplastic culverts are pipe sections in which the main load-carrying members are steel ribs or corrugations encapsulated by thermoplastic material that may brace the ribs or corrugations from distortion and buckling. This composite system should be evaluated independently for each manufacturer's pipe system. Designers should obtain the required mechanical properties directly from the pipe manufacturer to determine fill heights.

12.7.2.2—Thrust

The factored thrust, T_L , per unit length of wall shall be taken as:

$$T_L = \frac{P_{FD}(S)}{2} + \frac{P_{FL}(C_L)F_l}{2} \quad (12.7.2.2-1)$$

in which:

$$C_L = \ell_w \leq S \quad (12.7.2.2-2)$$

- for corrugated metal pipe:

$$F_l = \frac{0.75S}{\ell_w} \geq F_{\min} \quad (12.7.2.2-3)$$

$$F_{\min} = \frac{15}{12(S)} \geq 1 \quad (12.7.2.2-4)$$

- for long-span corrugated metal structures:

$$F_l = \frac{0.54(S)}{\frac{w_l}{12} + LLDF(H) + 0.03(S)} \quad (12.7.2.2-5)$$

where:

C_L = width of culvert on which live load is applied parallel to span (ft)

$LLDF$ = live load distribution factor, as specified in Article 3.6.1.2.6

C12.7.2.2

Factored vertical crown pressure is calculated as the factored free-field soil pressure at the elevation of the top of the structure, plus the factored live load pressure distributed through the soil cover to the top of the structure.

ℓ_w	=	live load patch length at depth, H , as specified in Article 3.6.1.2.6
P_{FD}	=	factored dead load vertical crown pressure, as specified in Article 12.12.3.4 with VAF taken as 1.0 and D_o taken as S (ksf)
P_{FL}	=	factored live load vertical crown pressure, as specified in Article 12.12.3.4 (ksf)
S	=	culvert span (ft)
T_L	=	factored thrust per unit length (kip/ft)
w_t	=	tire patch width, as specified in Article 3.6.1.2.5 (in.)

12.7.2.3—Wall Resistance

The factored axial resistance, R_n , per unit length of wall, without consideration of buckling, shall be taken as:

$$R_n = \phi F_y A \quad (12.7.2.3-1)$$

where:

A	=	wall area (in. ² /ft)
F_y	=	yield strength of metal (ksi)
ϕ	=	resistance factor, as specified in Article 12.5.5

12.7.2.4—Resistance to Buckling

The wall area, calculated using Eq. 12.7.2.3-1, shall be investigated for buckling. If $f_{cr} < F_y$, A shall be recalculated using f_{cr} in lieu of F_y .

$$\text{If } S < \left(\frac{r}{k}\right) \sqrt{\frac{24E_m}{F_u}}, \text{ then } f_{cr} = F_u - \frac{\left(\frac{F_u k S}{r}\right)^2}{48E_m} \quad (12.7.2.4-1)$$

$$\text{If } S > \left(\frac{r}{k}\right) \sqrt{\frac{24E_m}{F_u}}, \text{ then } f_{cr} = \frac{12E_m}{\left(\frac{kS}{r}\right)^2} \quad (12.7.2.4-2)$$

where:

S	=	diameter of pipe or span of plate structure (in.)
E_m	=	modulus of elasticity of metal (ksi)
F_u	=	tensile strength of metal (ksi)
f_{cr}	=	critical buckling stress (ksi)
r	=	radius of gyration of corrugation (in.)
k	=	soil stiffness factor, taken as 0.22

12.7.2.4.1—Critical Compressive Stress

For steel-reinforced thermoplastic culvert, stub compression test (AASHTO T 341) data shall be provided to establish the f_{cr} value of the wall profile being evaluated. If f_{cr} value is less than the value established by Article 12.7.2.4, it shall be used as the limiting critical compressive stress for the pipe wall.

C12.7.2.4

The use of 0.22 for the soil stiffness is thought to be conservative for the types of backfill material allowed for pipe and arch structures. This lower bound on soil stiffness has a long history of use in previous editions of the Standard Specifications.

12.7.2.5—Seam Resistance

For pipe fabricated with longitudinal seams, the factored resistance of the seam shall be sufficient to develop the factored thrust in the pipe wall, T_L .

12.7.2.6—Handling and Installation Requirements

Handling flexibility shall be indicated by a flexibility factor, determined as:

$$FF = \frac{S^2}{E_m I} \quad (12.7.2.6-1)$$

Values of the flexibility factors for handling and installation shall not exceed the values for steel and aluminum pipe and plate pipe structures as specified in Article 12.5.6.

12.7.2.7—Profile Evaluation for Steel-Reinforced Thermoplastic Culverts

To assure the adequacy of the thermoplastic liner, the culvert manufacturer shall provide the results of a three-dimensional finite element analysis of the profile that has been calibrated against results of full-scale tests. A minimum of two full-scale tests are required to properly calibrate the results of the finite element analysis. In particular, the measurement and prediction of the maximum strains within the profile shall be identified. The predicted long-term tensile strains within the profile shall be within the allowable limits for the high-density polyethylene (HDPE) material being used in the profile. The strain limits for polyethylene materials shall be taken as specified in Table 12.12.3.3-1.

Additionally, in order to establish the relative long-term interaction of the steel reinforcement with the HDPE profile, the stub compression test (AASHTO T 341) shall be performed utilizing stroke rates of 0.05 in./minute, 0.005 in./minute, and 0.0005 in./minute and the results compiled to determine if a reduction in the HDPE modulus results in a reduced result from the stub compression tests. If a reduction factor is deemed to be appropriate, the reduced value shall be used as described in Article 12.7.2.4.1.

12.7.3—Smooth Lined Pipe

Corrugated metal pipe composed of a smooth liner and corrugated shell attached integrally at helical seams, spaced not more than 30.0 in. apart, may be designed on the same basis as a standard corrugated metal pipe having the same corrugations as the shell and a weight per ft not less than the sum of the weights per ft of liner and helically corrugated shell.

The pitch of corrugations shall not exceed 3.0 in., and the thickness of the shell shall not be less than

C12.7.2.6

Transverse stiffeners may be used to assist corrugated structural plate structures to meet flexibility factor requirements.

C12.7.2.7

The full-scale tests should follow the loading conditions, measurements, and test methods consistent with those utilized in the research report *DuroMaxx Pipe Assessment* by I. D. Moore (24 in. – February 2009, 60 in. – August 2009) or similar approved method.

While the steel ribs or corrugations are the main load-carrying member of the culvert, the thermoplastic profile braces the steel ribs or corrugations from distortion or buckling under load and is critical to the pipe performance. The liner also serves to distribute the load between ribs or corrugations. A structural evaluation of

the profile alone is not required. However, an evaluation of the composite system of thermoplastic liner and steel rib or corrugation is necessary. It is important to assure that the tensile strains within the profile do not exceed the long-term strain capacity for the thermoplastic material used in the construction of the pipe.

60 percent of the total thickness of the equivalent standard pipe.

12.7.4—Stiffening Elements for Structural Plate Structures

The stiffness and flexural resistance of structural plate structures may be increased by adding circumferential stiffening elements to the crown. Stiffening elements shall be symmetrical and shall span from a point below the quarter-point on one side of the structure, across the crown, and to the corresponding point on the opposite side of the structure.

12.7.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 26 of the *AASHTO LRFD Bridge Construction Specifications*.

12.8—LONG-SPAN STRUCTURAL PLATE STRUCTURES

12.8.1—General

The provisions herein and in Article 12.7 shall apply to the structural design of buried long-span structural plate corrugated metal structures.

The following shapes, illustrated in Figure 12.8.1-1, shall be considered long-span structural plate structures:

- Structural plate pipe and arch shaped structures that require the use of special features specified in Article 12.8.3.5, and
- Special shapes of any size having a radius of curvature greater than 13.0 ft in the crown or side plates. Metal box culverts are not considered long-span structures and are covered in Article 12.9.

C12.7.4

Acceptable stiffening elements are:

- Continuous longitudinal structural stiffeners connected to the corrugated plates at each side of the top arc: metal or reinforced concrete, either singly or in combination; and
- Reinforcing ribs formed from structural shapes, curved to conform to the curvature of the plates, fastened to the structure to ensure integral action with the corrugated plates, and spaced at such intervals as necessary.

C12.8.1

These structures become part of a composite system comprised of the metal structure section and the soil envelope, both of which contribute to the behavior of the system.

Figure 12.8.1-1—Long-Span Shapes

12.8.2—Service Limit State

No service limit state criteria need be required.

12.8.3—Safety Against Structural Failure

With the exception of the requirements for buckling and flexibility, the provisions of Article 12.7 shall apply, except as described herein.

Dimensions and properties of structure cross-sections, minimum seam strength, mechanical and chemical requirements, and bolt properties for long-span structural plate sections shall be taken as specified in Appendix A12 or as described herein.

12.8.3.1—Section Properties

12.8.3.1.1—Cross-Section

The provisions of Article 12.7 shall apply, except as specified.

Structures not described herein shall be regarded as special designs.

C12.8.2

Soil design and placement requirements for long-span structures are intended to limit structure deflections. The contract documents should require that construction procedures be monitored to ensure that severe deformations do not occur during backfill placement and compaction.

C12.8.3

Most long-span culverts are designed for a larger load factor; however, the limit states of flexure and buckling are ignored for those structures. Considering these limit states reduces the uncertainty in the final design and permits use of a lower load factor. This is the same approach used for metal box culverts.

C12.8.3.1.1

Table A12-3 shall apply. Minimum requirements for section properties shall be taken as specified in Table 12.8.3.1.1-1. Covers that are less than that shown in Table 12.8.3.1.1-1 and that correspond to the minimum plate thickness for a given radius may be used if ribs are used to stiffen the plate. If ribs are used, the plate thickness may not be reduced below the minimum shown for that radius, and the moment of inertia of the rib and plate section shall not be less than that of the thicker unstiffened plate corresponding to the fill height. Use of soil cover less than the minimum values shown for a given radius shall require a special design.

Designs not covered in Table 12.8.3.1.1-1 should not be permitted unless substantiated by documentation acceptable to the Owner.

Sharp radii generate high soil pressures. Avoid high ratios when significant heights of fill are involved.

Table 12.8.3.1.1-1—Minimum Requirements for Long-Span Structures with Acceptable Special Features

Top Arc Minimum Thickness (in.)					
Top Radius (ft)	≤15.0	15.0–17.0	17.0–20.0	20.0–23.0	23.0–25.0
6 in. × 2 in. Corrugated Steel Plate—Top Arc Minimum Thickness (in.)	0.111	0.140	0.170	0.218	0.249
Geometric Limits					
The following geometric limits shall apply:					
- Maximum plate radius—25.0 ft - Maximum central angle of top arc—80.0 degrees - Minimum ratio, top arc radius to side arc radius—2 - Maximum ratio, top arc radius to side arc radius—5					
Minimum Cover (ft)					
Top Radius (ft)	≤ 15.0	15.0–17.0	17.0–20.0	20.0–23.0	23.0–25.0
Steel thickness without ribs (in.)					
0.111	2.5	—	—	—	—
0.140	2.5	3.0	—	—	—
0.170	2.5	3.0	3.0	—	—
0.188	2.5	3.0	3.0	—	—
0.218	2.0	2.5	2.5	3.0	—
0.249	2.0	2.0	2.5	3.0	4.0
0.280	2.0	2.0	2.5	3.0	4.0

12.8.3.1.2—Shape Control

The requirements of Articles 12.7.2.4 and 12.7.2.6 shall not apply for the design of long-span structural plate structures.

12.8.3.1.3—Mechanical and Chemical Requirements

Tables A12-3, A12-8, and A12-10 shall apply.

12.8.3.2—Thrust

The factored thrust in the wall shall be determined by Eq. 12.7.2.2-1, except the value of S in the Equation shall be replaced by twice the value of the top arc radius, R_T .

12.8.3.3—Wall Area

The provisions of Article 12.7.2.3 shall apply.

12.8.3.4—Seam Strength

The provisions of Article 12.7.2.5 shall apply.

12.8.3.5—Acceptable Special Features

12.8.3.5.1—Continuous Longitudinal Stiffeners

Continuous longitudinal stiffeners shall be connected to the corrugated plates at each side of the top arc. Stiffeners may be metal or reinforced concrete either singly or in combination.

12.8.3.5.2—Reinforcing Ribs

Reinforcing ribs formed from structural shapes may be used to stiffen plate structures. Where used, they should be:

- curved to conform to the curvature of the plates,
- fastened to the structure as required to ensure integral action with the corrugated plates, and
- spaced at such intervals as necessary to increase the moment of inertia of the section to that required for design.

12.8.4—Safety Against Structural Failure—Foundation Design

12.8.4.1—Settlement Limits

A geotechnical survey of the site shall be made to determine that site conditions will satisfy the requirement that both the structure and the critical backfill zone on each side of the structure be properly supported. Design shall satisfy the requirements of Article 12.6.2.2, with the following factors to be considered when establishing settlement criteria:

- Once the structure has been backfilled over the crown, settlement of the supporting backfill relative to the structure must be limited to control drag loads. If the sidefill will settle more than the structure, a detailed analysis may be required.

C12.8.4.1

Once the top arc of the structure has been backfilled, drag loads may occur if the structure backfill settles into the foundation more than the structure. This results in the structure carrying more soil load than the overburden directly above it. If undertaken prior to erecting the structure, site improvements such as surcharging, foundation compacting, etc., often adequately correct these conditions.

- H_1 = height of cover above the footing to traffic surface (ft)
 H_2 = height of cover from the springline of the structure to traffic surface (ft)
 L_w = lane width (ft)
 γ_s = unit weight of soil (kef)
 S = span (ft)

The distribution of live load through the fill shall be based on any accepted methods of analysis.

Figure C12.8.4.2-1—Live-Load Footing Reaction Due to Axles of the Design Truck, per Footing

12.8.4.3—Footing Design

Reinforced concrete footings shall be designed in accordance with Article 10.6 and shall be proportioned to satisfy settlement requirements of Article 12.8.4.1.

12.8.5—Safety Against Structural Failure—Soil Envelope Design

12.8.5.1—General

Structural backfill material in the envelope around the structure shall satisfy the requirements of Article 12.4.1.3 for long-span structures. The width of the envelope on each side of the structure shall be proportioned to limit shape change during construction activities outside the envelope and to control deflections at the service limit state.

12.8.5.2—Construction Requirements

The structural backfill envelope shall either extend to the trench wall and be compacted against it or extend a distance adequate to protect the shape of the structure from construction loads. The remaining trench width may be filled with suitable backfill material compacted to satisfy the requirements of Article 12.8.5.3. In embankment conditions, the minimum structural backfill width shall be taken as 6.0 ft. Where dissimilar materials not meeting geotechnical filter criteria are used adjacent

C12.8.5.1

Structure erection, backfill, and construction shall meet all the requirements of Section 26 of the *AASHTO LRFD Bridge Construction Specifications*. The performance of the structure depends upon the in-situ embankment or other fill materials beyond the structural backfill. Design must consider the performance of all materials within the zone affected by the structure.

C12.8.5.2

The purpose of this provision is to control shape change from construction activities outside the envelope in trench conditions.

to each other, a suitable geotextile shall be provided to avoid migration.

12.8.5.3—Service Requirements

The width of the envelope on each side of the structure shall be adequate to limit horizontal compression strain to one percent of the structure's span on each side of the structure.

Determination of the horizontal compressive strain shall be based on an evaluation of the width and quality of the structural backfill material selected as well as the in-situ embankment or other fill materials within the zone on each side of the structure taken to extend to a distance equal to the rise of the structure, plus its cover height as indicated in Figure 12.8.5.3-1.

Forces acting radially off the small radius corner arc of the structure at a distance, d_1 , from the structure may be taken as:

$$P_1 = \frac{T}{R_c + d_1} \quad (12.8.5.3-1)$$

where:

- P_1 = horizontal pressure from the structure at a distance, d_1 (ksf)
- d_1 = distance from the structure (ft)
- T = total dead load and live load thrust in the structure (see Article 12.8.3.2) (kip/ft)
- R_c = corner radius of the structure (ft)

The required envelope width adjacent to the pipe, d , may be taken as:

$$d = \frac{T}{P_{Brg}} - R_c \quad (12.8.5.3-2)$$

where:

- d = required envelope width adjacent to the structure (ft)
- P_{Brg} = allowable bearing pressure to limit compressive strain in the trench wall or embankment (ksf)

The structural backfill envelope shall be taken to continue above the crown to the lesser of:

- the minimum cover level specified for that structure,
- the bottom of the pavement or granular base course where a base course is present below the pavement, or
- the bottom of any relief slab or similar construction where one is present.

C12.8.5.3

The purpose of this provision is to limit deflections under service loads. The limit on soil compression limits the theoretical design increase in span to two percent. This is a design limit, not a performance limit. Any span increase that occurs is principally due to the consolidation of the side support materials as the structure is loaded during backfilling. These are construction movements that attenuate when full cover is reached.

Eqs. 12.8.5.3-1 and 12.8.5.3-2 conservatively assume that the pressure from the structure acts radially outward from the corner arc without further dissipation. Figure C12.8.5.3-1 provides the geometric basis of these Equations.

Figure C12.8.5.3-1—Radial Pressure Diagram

Figure 12.8.5.3-1—Typical Structural Backfill Envelope and Zone of Structure Influence

12.8.6—Safety Against Structural Failure—End Treatment Design

12.8.6.1—General

End treatment selection and design shall be considered as an integral part of the structural design.

12.8.6.2—Standard Shell End Types

The standard end types for the corrugated plate shell shall be taken to be those shown in Figure 12.8.6.2-1.

C12.8.6.1

Proper end treatment design ensures proper support of the ends of the structure while providing protection from scour, hydraulic uplift, and loss of backfill due to erosion forces.

C12.8.6.2

Standard end types refer to the way the structural plate structure's ends are cut to match the fill slope, stream banks, etc. While the type of end selected may have aesthetic or hydraulic considerations, the structural design must ensure adequate structural strength and protection from erosion. Hydraulic considerations may require wingwalls, etc.

Step bevel, full bevel, and skewed ends all involve cutting the plates within a ring. Each has its own structural considerations.

The square end is the simplest arrangement. No plates are cut and the barrel retains its integrity.

(A) SQUARE END

(B) STEP BEVEL

(C) SKEW CUT END
(REQUIRES FULL HEADWALL)**Figure 12.8.6.2-1—Standard Structure End Types**

The following considerations shall apply to step bevels:

- The rise of the top step shall be equal to or greater than the rise of the top arc, i.e., plates in the top arc are left uncut.

Step bevels cut the corner (and side on pear and high profile arch shapes) plates on a diagonal (bevel) to match the fill slope.

Step bevels are widely used. The plates in the large radius top arc are left uncut to support the sides of the structure near each end.

- For structures with inverts, the bottom step shall satisfy the requirements for a top step.
- For arches, the bottom step shall be a minimum of 6.0 in. high.
- The slope of the cut plates generally should be no flatter than 3:1.
- The upper edge of the cut plates shall be bolted to and supported by a structural concrete slope collar, slope pavement, or similar device.

Full bevel ends shall be used in special designs only. Structures with full inverts shall have a bottom step conforming to the requirements for step bevel ends.

The bevel cut edge of all plates shall be supported by a suitable, rigid concrete slope collar.

Skew cut ends shall be fully connected to and supported by a headwall of reinforced concrete or other rigid construction. The headwall shall extend an adequate distance above the crown of the structure to be capable of reacting the ring compression thrust forces from the cut plates. In addition to normal active earth and live load pressures, the headwall shall be designed to react a component of the radial pressure exerted by the structure, as specified in Article 12.8.5.

12.8.6.3—Balanced Support

Designs and details shall provide soil support that is relatively balanced from side to side, perpendicularly across the structure. In lieu of a special design, slopes running perpendicularly across the structure shall not exceed ten percent for cover heights of 10.0 ft or less and 15 percent for higher covers.

When a structure is skewed to an embankment, the fill shall be detailed to be warped to maintain balanced support and to provide an adequate width of backfill and embankment soil to support the ends.

12.8.6.4—Hydraulic Protection

12.8.6.4.1—General

In hydraulic applications, provisions shall be made to protect the structure, taken to include the shell, footings, structural backfill envelope, and other fill materials within the zone influenced by the structure.

Invert plates must be left uncut to avoid leaving the invert as triangular shaped elements, when viewed in plan, running upstream and downstream.

Diagonally-cut corner and side plates become a retaining wall, supporting the fill slope beside them. They must be provided with suitable, rigid support at the top that acts as a top wale beam and be limited in length. These plates have limited longitudinal strength and inadequate bending strength or fixity to act as a cantilevered retaining wall.

When a full bevel cuts the top plates, additional support is necessary to backfill the structure. Typically, the top step is left in place and field cut only after a suitable rigid concrete slope collar has been poured and adequately cured.

Ring compressive thrust forces act circumferentially around the structure following the corrugations. At the skew cut ends of the plate, these forces act tangentially to the plate and must be resisted by a headwall. Additionally, because a skew cut structure is not perpendicular to the headwall, a portion of the radial pressure from the structure acts normal to the back of the headwall.

C12.8.6.3

Flexible structures have relatively low bending strength. If the earth support is not balanced, the structure in effect becomes a retaining wall. An excessive imbalance causes shape distortion and ultimately failure.

When a structure is skewed to an embankment, two diagonally opposite areas at the ends of the structure are not adequately supported. This must be corrected by extending the embankment an adequate distance out beside the structure.

In lieu of a special design, details provided in Article C12.6.8.2 may be considered.

A properly warped embankment is characterized by equal elevation topographical lines crossing the structure perpendicularly and extending beyond it a suitable distance so that the volume of earth included in the warp provides a gravity retaining wall capable of supporting the radial pressures from the structure with adequate safety.

12.8.6.4.2—Backfill Protection

Design or selection of backfill gradation shall include consideration of loss of backfill integrity due to piping. If materials prone to piping are used, the structure and ends of the backfill envelope shall be adequately sealed to control soil migration, infiltration, or both.

C12.8.6.4.2

Backfill piping and migration is always a major consideration in selecting its specific gradation. The ends of the backfill envelope may be sealed using one or a combination of a compacted clay cap, concrete slope pavements, grouted riprap, headwalls to the design storm elevation, and similar details.

12.8.6.4.3—Cut-Off (Toe) Walls

All hydraulic structures with full inverts shall be designed and detailed with upstream and downstream cut-off walls. Invert plates shall be bolted to cut-off walls at a maximum 20.0-in. center-to-center spacing using 0.75-in. bolts.

The cut-off wall shall extend to an adequate depth to limit hydraulic percolation to control uplift forces, as specified in Article 12.8.6.4.4, and scour, as specified in Article 12.8.6.4.5.

12.8.6.4.4—Hydraulic Uplift

Hydraulic uplift shall be considered for hydraulic structures with full inverts where the design flow level in the pipe can drop quickly. The design shall provide means to limit the resulting hydraulic gradients, with the water level higher in the backfill than in the pipe, so that the invert will not buckle and the structure will not float. Buckling may be evaluated as specified in Article 12.7.2.4, with the span of the structure taken as twice the invert radius.

C12.8.6.4.4

Structural plate structures are not watertight and allow for both infiltration and exfiltration through the structure's seams, bolt holes, and other discontinuities. Where uplift can be a concern, designs typically employ adequate cut-off walls and other means to seal off water flow into the structural backfill.

12.8.6.4.5—Scour

Scour design shall satisfy the requirements of Article 12.6.5. Where erodible soils are encountered, conventional means of scour protection may be employed to satisfy these requirements.

Deep foundations such as piles or caissons should not be used unless a special design is provided to consider differential settlement and the inability of intermittent supports to retain the structural backfill if scour proceeds below the pile cap.

C12.8.6.4.5

Structures with full inverts eliminate footing scour considerations when adequate cut-off walls are used. For arches, reinforced concrete invert pavements, riprap, grouted riprap, etc., can be employed to provide scour protection.

12.8.7—Concrete Relieving Slabs

Concrete relieving slabs may be used to reduce moments in long-span structures.

The length of the concrete relieving slab shall be at least 2.0 ft greater than the span of the structure. The relieving slab shall extend across the width subject to vehicular loading, and its depth shall be determined as specified in Article 12.9.4.6.

C12.8.7

Application of a typical concrete relieving slab is shown in Figure 12.9.4.6-1.

12.8.8—Construction and Installation

The construction documents shall require that construction and installation conform to Section 26 of the *AASHTO LRFD Bridge Construction Specifications*.

12.8.9—Deep Corrugated Structural Plate Structures

12.8.9.1—General

The provisions of this Section shall apply to the structural design of buried, deep corrugated structural plate. These structures are designed as long-span culverts but must also meet provisions for flexure and general buckling. These structures may be manufactured in multiple shapes. Flexibility criteria and special features are not applicable to deep corrugated structures. The rise to span limit of 0.3 in Article 12.7.1 does not apply.

C12.8.9.1

The design of long-span metal structures in these Specifications is currently completed with empirical procedures that limit the shapes and plate thicknesses for the structures and require special features. If the provisions are met, then no design is required for flexure or buckling. NCHRP Report 473 recommends updating design provisions for long-span structures and included provisions to allow structures outside the current limits for long-span structures but included limit states for flexure and general buckling. Article 12.8.9 provides a design procedure for such structures. The provisions of Article 12.8.9 apply to structures fabricated from deep corrugated plate, defined in Article 12.2 as corrugated plate with a corrugation depth greater than 5.0 in.

12.8.9.2—Width of Structural Backfill

12.8.9.2.1—Deep Corrugated Structures with Ratio of Crown Radius to Haunch Radius ≤ 5

The structural backfill zone around deep corrugated structures with ratio of crown radius to haunch radius ≤ 5 shall extend to at least the minimum cover height above the crown. At the sides of the structure, the minimum extent of the structural backfill from the outside of the structure springline shall meet one of the following:

- Structure constructed in a trench in which the natural soil is at least as stiff as the engineered soil: 8.0 ft, or
- Structure constructed in an embankment or in a trench in which the natural soil is less stiff than the engineered soil: one-third of the structure span but not less than 10.0 ft or more than 17.0 ft

but not less than required by culvert-soil interaction analysis.

12.8.9.2.2—Deep Corrugated Structures with Ratio of Crown Radius to Haunch Radius > 5

The structural backfill zone around deep corrugated structures with ratio of crown radius to haunch radius > 5 shall extend to at least the minimum cover height above the crown. At the sides of the structure, the minimum extent of structural backfill shall meet one of the following:

- for structures with spans up to and including 25.0 ft 5.0 in. and less than 5.0 ft of cover: a minimum of 3.5 ft beyond the widest part of the structure, or
- for structures with spans up to and including 25.0 ft 5.0 in. and greater than 5.0 ft of cover and for structures with spans greater than 25.0 ft 5.0 in. at all depths of fill: a minimum of one-fifth of the structure span beyond the widest part of the structure but not less than 5.0 ft nor more than 17.0 ft.

but not less than required by culvert-soil interaction analysis.

12.8.9.3—Safety Against Structural Failure

Deep corrugated structures shall be designed in accordance with the provisions of Articles 12.8.1 to 12.8.8, except for modified or additional provisions as follow.

12.8.9.3.1—Structural Plate Requirements

Deep corrugated structural plate used to manufacture structures designed under this section shall meet the requirements of AASHTO M 167M/M 167.

Sections may be stiffened. If stiffening is provided by ribs, the ribs shall be bolted to the structural plate corrugation prior to backfilling using a bolt spacing of not more than 16.0 in. for 15.0 by 5.5 in. and 16.0 by 6.0 in. corrugations, or 20.0 in. for 20.0 by 9.5 in. corrugations. The cross-section properties in Table A12-14 shall apply.

12.8.9.3.2—Structural Analysis

Structures designed under the provisions of this Article shall be analyzed by accepted finite element analysis methods that consider both the strength and stiffness properties of the structural plate and the soil. The analysis shall produce thrust and moments for use in design. The analysis must consider all applicable combinations of construction, earth, live, and other applicable load conditions. Springline thrust due to earth load used in wall resistance, buckling, and seam resistance design shall not be less than 1.3 times the earth load thrust computed in accordance with Article 12.7.2.2.

12.8.9.4—Minimum Height of Fill

For deep corrugated structural plate structures, the minimum height of cover, H_D , shall be the smaller of 3.0 ft or the limits for long-span structural plate structures based on top radius and plate thickness in Table 12.8.3.1.1-1. For deep corrugated structures with the ratio of crown radius to haunch radius >5 , minimum cover shall be 1.5 ft for spans ≤ 25.0 ft 5.0 in. and 2.0 ft for spans > 25.0 ft 5.0 in. The minimum height of cover in all cases shall not

C12.8.9.3.1

It is acceptable to measure bolt spacing either at the centroid or crest of the structural plate corrugation.

C12.8.9.3.2

The computer program CANDE was developed by the FHWA specifically for the design of buried culverts and has the necessary soil and culvert material models to complete designs.

Because distribution of live loads to all long-span culverts does not consider arching, application of the 1.3 factor should be limited to just the earth load component of Article 12.7.2.2.

be less than that required by culvert-soil interaction analysis.

12.8.9.5—Combined Thrust and Moment

The combined effects of moment and thrust at all stages of construction shall meet the following requirement:

$$\left(\frac{T_f}{R_t}\right)^2 + \left|\frac{M_u}{M_n}\right| \leq 1.00 \quad (12.8.9.5-1)$$

where:

- T_f = factored thrust
- R_t = factored thrust resistance = $\phi_b F_y A$
- M_u = factored applied moment
- M_n = factored moment resistance = $\phi_b M_p$
- M_p = plastic moment capacity of section

C12.8.9.5

The equation for combined moment and thrust is taken from the provision for buried structures in the Canadian Highway Bridge Design Code CSA-S6-06. The equation is more liberal than the AASHTO equations for combined moment and thrust (axial force) for steel structures in Article 12.8.9.6. However, the provisions in Article 12.8.9.6 are based on strong axis bending of wide flange sections. The equation for combined moment and thrust is taken from the provision for buried structures in the Canadian Highway Bridge Design Code CSA-S6-06. The equation is more liberal than the AASHTO equations for combined moment and thrust (axial force) for steel structures in Article 6.9.2.2. However, the provisions in Article 6.9.2.2 are based on strong axis bending of wide flange sections.

Figure C12.8.9.5-1—Strength Curves for Member of Zero Length:
(a) Strong-Axis; (b) Weak-Axis from White and Clarke (1997)

12.8.9.6—Global Buckling

The factored thrust in the culvert wall under the final installed condition shall not exceed the nominal resistance to general buckling capacity of the culvert, computed as:

$$R_b = 1.2\phi_b C_n \left(E_p I_p \right)^{\frac{1}{3}} \left(\phi_s M_s K_b \right)^{\frac{2}{3}} R_h \quad (12.8.9.6-1)$$

where:

- R_b = nominal axial force in culvert wall to cause general buckling
- ϕ_b = resistance factor for general buckling
- C_n = scalar calibration factor to account for some nonlinear effects = 0.55
- E_p = modulus of elasticity of pipe wall material (ksi)
- I_p = moment of inertia of stiffened culvert wall per unit length (in.⁴)
- ϕ_s = resistance factor for soil
- M_s = constrained modulus of embedment computed based on the free field vertical stress at a depth halfway between the top and springline of the structure, as specified in Table 12.12.3.5-1
- K_b = $(1 - 2\nu) / (1 - \nu^2)$
- ν = Poisson's ratio of soil
- R_h = correction factor for backfill geometry
= $11.4 / (11 + S/H)$
- S = culvert span (ft)
- H = height of fill over top of culvert (ft)

12.8.9.7—Connections

The factored moment resistance of longitudinal connections shall be at least equal to the factored applied moment but not less than the greater of:

- 75 percent of the factored moment resistance of the member or
- the average of the factored applied moment and the factored moment resistance of the member.

Moment resistance of connections may be obtained from qualified tests or published standards.

12.9—STRUCTURAL PLATE BOX STRUCTURES**12.9.1—General**

The design method specified herein shall be limited to height of cover from 1.4 to 5.0 ft.

The provisions of this Article shall apply to the design of structural plate box structures, hereinafter called “metal box culverts.” The provisions of Articles 12.7 and 12.8 shall not apply to metal box culvert designs, except as noted.

If rib stiffeners are used to increase the flexural resistance and moment capacity of the plate, the transverse

C12.8.9.6

The proposed buckling equations are taken from the recommendations of NCHRP Report 473, *Recommended Specifications for Large-Span Culverts*.

Global buckling of deep corrugated structures occurs over a long wavelength; thus, the soil modulus computed at a depth halfway between the top and springline of the structure is representative of the overall soil resistance to buckling.

C12.8.9.7

The *AASHTO LRFD Bridge Construction Specifications* require longitudinal joints to be staggered to avoid a continuous line of bolts on a structure.

C12.9.1

These Specifications are based on three types of data:

- finite element soil–structure interaction analyses,
- field loading tests on instrumented structures, and
- extensive field experience.

Structural plate box culverts are composite-reinforced rib plate structures of approximately

stiffeners shall consist of structural steel or aluminum sections curved to fit the structural plates. Ribs shall be bolted to the plates to develop the plastic flexural resistance of the composite section. Spacing between ribs shall not exceed 2.0 ft on the crown and 4.5 ft on the haunch. Rib splices shall develop the plastic flexural resistance required at the location of the splice.

12.9.2—Loading

For live loads, the provisions of Article 3.6.1 shall apply.

Unit weights for soil backfill, other than 0.12 kcf, may be considered as specified in Article 12.9.4.2.

12.9.3—Service Limit State

No service limit state criteria need be applied in the design of box culvert structures.

12.9.4—Safety Against Structural Failure

12.9.4.1—General

The resistance of corrugated box culverts shall be determined at the strength limit state in accordance with Articles 12.5.3, 12.5.4, and 12.5.5 and the requirements specified herein.

Box culvert sections for which these Articles apply are defined in Figure 12.9.4.1-1 and Table 12.9.4.1-1. Table A12-10 shall apply.

rectangular shape. They are intended for shallow covers and low, wide waterway openings. The shallow covers and extreme shapes of box culverts require special design procedures.

Metal box culverts differ greatly from conventional metal culvert shapes. Metal box culverts are relatively flat at the top and require a large flexural capacity due to extreme geometry and shallow depths of cover of 5.0 ft or less. Analyses over the range of sizes permitted under these Specifications indicate that flexural requirements govern the choice of section in all cases. The effects of thrust are negligible in comparison with those of flexure. This difference in behavior requires a different approach in design.

For information regarding the manufacture of structures and structural components referred to herein, see AASHTO M 167M/M 167 (ASTM A761/A761M) for steel and M 219 (ASTM B746) for aluminum.

C12.9.2

The earth loads for the design procedure described herein are based upon soil backfill having a standard unit weight, γ_s , of 0.12 kcf.

C12.9.3

Soil design and placement requirements for box culvert structures can limit structure deflections satisfactorily. The contract documents should require that construction procedures be monitored to ensure that severe deformations do not occur during backfill placement and compaction, in which case no deflection limits should be imposed on the completed structure.

C12.9.4.1

Finite element analyses covering the range of metal box culvert shapes described in this Article have shown that flexural requirements govern the design in all cases. Effects of thrust are negligible when combined with flexure.

The structural requirements for metal box culverts are based on the results of finite element analyses and field measurements of in-service box culverts.

Figure 12.9.4.1-1—Geometry of Box Culverts

Table 12.9.4.1-1—Geometric Requirements for Box Culverts with Spans from 8 ft 9 in. to 25 ft 5 in.

Span, S : 8 ft 9 in. to 25 ft 5 in.
Rise, R : 2 ft 6 in. to 10 ft 6 in.
Radius of crown, $r_c \leq 24$ ft 9 $\frac{1}{2}$ in.
Radius of haunch, $r_h \geq 2$ ft 6 in.
Haunch radius included angle, Δ , 50° to 70°
Length of leg, D , measured to the bottom of the plate, may vary from 4 $\frac{3}{4}$ to 71 in.
Minimum length of rib on leg, L , least of 19.0 in., $(D - 3.0)$ in., or to within 3.0 in. of the top of a concrete footing

Table 12.9.4.1-2—Geometric Requirements for Box Culverts with Spans from 25 ft 6 in. to 36 ft 0 in.

Span, S : 25 ft 6 in. to 36 ft 0 in.
Rise, R : 5 ft 7 in. to 14 ft 0 in.
Radius of crown, $r_c \leq 26$ ft 4 in.
Radius of haunch, $r_h \geq 3$ ft 8 in.
Haunch radius included angle, Δ : 48° to 68°
Length of leg, D , measured to the bottom of the plate, may vary from 4 $\frac{3}{4}$ to 71 in.
Minimum length of rib on leg, L , least of 28.0 in., $(D - 3.0)$ in., or to within 3.0 in. of the top of a concrete footing

The flexural resistance of corrugated plate box structures shall be determined using the specified yield strength of the corrugated plate.

The flexural resistance of plate box structures with ribbed sections shall be determined using specified yield strength values for both rib and corrugated shell. Computed values may be used for design only after confirmation by representative flexural testing. Rib splices shall develop the plastic moment capacity required at the location of the splice.

12.9.4.2—Moments Due to Factored Loads

Unfactored crown and haunch dead and live load moments, M_{dc} and $M_{\ell c}$, may be taken as:

For spans ≤ 25.0 ft 5.0 in.:

C12.9.4.2

Structural plate box structures not meeting the geometric requirements of Article 12.9.4.1 may be analyzed with finite element methods that incorporate the effects of soil–structure interaction.

$$M_{dl} = \gamma_s \left\{ S^3 [0.0053 - 0.00024(S-12)] + 0.053(H-1.4)S^2 \right\} \quad (12.9.4.2-1)$$

For spans from 25.0 ft 6.0 in. through 36.0 ft 0 in. with a geometry profile that meets $r_c = 26.0$ ft, $r_h = 3.0$ ft 8 $\frac{7}{8}$ in., and $\Delta = 49.16$ degrees:

$$M_{dl} = \gamma_s \left\{ S^3 [0.00194 - 0.0002(S-26)(H-1.1)] + (H-1.4) [0.053S^2 + 0.6(S-26)^2] \right\} \quad (12.9.4.2-2)$$

$$M_{ll} = C_1 (K_1 / K_2) S A_L \quad (12.9.4.2-3)$$

where:

M_{dl} = sum of the nominal crown and haunch dead load moments (kip-ft/ft)

M_{ll} = sum of the nominal crown and haunch live load moments (kip-ft/ft)

S = box culvert span (ft)

γ_s = soil unit weight (kcf)

H = height of cover from the box culvert rise to top of pavement (ft)

A_L = sum of all axle loads in an axle group including multiple presence factor and load modifier (kip)

C_1 = 1.0 for single axles and per Table 12.9.4.2-1 for design tandem

K_1 = adjustment factor for span and height of fill, per Eqs. 12.9.4.2-4 and 12.9.4.2-5

K_2 = adjustment factor for height of fill, per Eqs. 12.9.4.2-6 and 12.9.4.2-7

in which:

$$K_1 = \frac{0.08}{\left(\frac{H}{S}\right)^{0.2}}, \text{ for } 8 \leq S < 20 \quad (12.9.4.2-4)$$

$$K_1 = \frac{0.08 - 0.002(S-20)}{\left(\frac{H}{S}\right)^{0.2}}, \text{ for } 20 \leq S \leq 36 \quad (12.9.4.2-5)$$

$$K_2 = 0.54H^2 - 0.4H + 5.05, \text{ for } 1.4 \leq H < 3.0 \quad (12.9.4.2-6)$$

$$K_2 = 1.90H + 3, \text{ for } 3.0 \leq H \leq 5.0 \quad (12.9.4.2-7)$$

Table 12.9.4.2-1—Adjustment Coefficient Values, C_1 , for Design Tandem Truck Loading

Depth (ft)	Span (ft)				
	8.75	10.17	20.08	30.08	35.25
1.4	0.52	0.56	0.76	0.82	0.67
2	0.53	0.55	0.79	0.85	0.69
3	0.58	0.67	0.82	0.90	0.73
5	0.72	0.69	0.83	0.88	0.73

Note: Linear interpolation may be used to determine the C_1 values for intermediate spans and depths of fill.

Unless otherwise specified, the design truck specified in Article 3.6.1.2.2 should be assumed to have four wheels on an axle. The design tandem specified in Article 3.6.1.2.3 should be assumed to be an axle group consisting of two axles with four wheels on each axle.

The factored moments, M_{dtu} and M_{ltu} , as referred to in Article 12.9.4.3, shall be determined using the appropriate load factors specified in Tables 3.4.1-1 and 3.4.1-2. The factored reactions shall be determined by factoring the reactions specified in Article 12.9.4.5.

12.9.4.3—Plastic Moment Resistance

The plastic moment resistance of the crown, M_{pc} , and the plastic moment resistance of the haunch, M_{ph} , shall not be less than the proportioned sum of adjusted dead and live load moments. The values of M_{pc} and M_{ph} shall be determined as follows:

$$M_{pc} \geq C_H P_c (M_{dtu} + M_{ltu}) \quad (12.9.4.3-1)$$

$$M_{ph} \geq C_H (1.0 - P_c) (M_{dtu} + R_H M_{ltu}) \quad (12.9.4.3-2)$$

where:

C_H = crown soil cover factor, specified in Article 12.9.4.4

P_c = allowable range of the ratio of total moment carried by the crown, as specified in Table 12.9.4.3-1

R_H = acceptable values of the haunch moment reduction factor, as specified in Table 12.9.4.3-2

M_{dtu} = factored dead load moment, as specified in Article 12.9.4.2 (kip-ft)

M_{ltu} = factored live load moment, as specified in Article 12.9.4.2 (kip-ft)

C12.9.4.3

Some discretion is allowed relative to the total flexural capacity assigned to the crown and haunches of box culverts.

The distribution of moment between the crown and haunch, described in Article C12.9.4.2, is accomplished in the design using the crown moment proportioning factor, P_c , which represents the proportion of the total moment that can be carried by the crown of the box culvert and that varies with the relative flexural capacities of the crown and haunch components.

The requirements given herein can be used to investigate products for compliance with these Specifications. Using the actual crown flexural capacity, M_{pc} , provided by the metal box structure under consideration and the loading requirements of the application, Eq. 12.9.4.3-1 can be solved for the factor P_c , which should fall within the allowable range of Table 12.9.4.3-1. Knowing P_c , Eq. 12.9.4.3-2 can be solved for M_{ph} , which should not exceed the actual haunch flexural resistance provided by the structure section. If Eq. 12.9.4.3-1 indicates a higher value of P_c than permitted by the allowable ranges in Table 12.9.4.3-1, the actual crown is over designed, which is acceptable. However, in this case, only the maximum value of P_c , allowed by Table 12.9.4.3-1, should be used to calculate the required M_{ph} from Eq. 12.9.4.3-2.

Table 12.9.4.3-1—Crown Moment Proportioning Values, P_c , for Spans ≤ 25.0 ft 5.0 in.

Span (ft)	Allowable Range of P_c
<10.0	0.55–0.70
10.0–15.0	0.50–0.70
15.0–20.0	0.45–0.70
20.0–25.4	0.45–0.60

Table 12.9.4.3-2—Crown Moment Positioning Values, P_c , for Spans from 25.0 ft 6.0 in. to 36.0 ft 0.0 in.

Height of Fill (ft)	Allowable Range of P_c
1.4–2.5	0.55–0.65
2.5–4.0	0.45–0.55
4.0–5.0	0.35–0.55

Table 12.9.4.3-3—Haunch Moment Reduction Values, R_H , for Spans ≤ 25.0 ft 5.0 in.

	Cover Depth (ft)			
	1.4	2.0	3.0	4.0 to 5.0
R_H	0.66	0.74	0.87	1.00

For spans from 25.0 ft 6.0 in. to 36.0 ft 0.0 in., $R_H = 1.0$ for all cover depths.

12.9.4.4—Crown Soil Cover Factor, C_H

For depths of soil cover greater than or equal to 3.5 ft, the crown soil cover factor, C_H , shall be taken as 1.0.

For crown cover depth between 1.4 and 3.5 ft, the crown soil cover factor shall be taken as:

$$C_H = 1.15 - \left(\frac{H - 1.4}{14} \right) \quad (12.9.4.4-1)$$

where:

H = height of cover over crown (ft)

12.9.4.5—Footing Reactions

Reactions at the box culvert footing shall be determined as:

$$V = \gamma_s \left(\frac{HS}{2.0} + \frac{S^2}{40.0} \right) + \frac{A_L}{8 + 2(H + R)} \quad (12.9.4.5-1)$$

where:

V = unfactored footing reaction (kip/ft)
 γ_s = unit weight of backfill (pcf)
 H = depth of cover over crown (ft)
 R = rise of culvert (ft)
 S = span (ft)
 A_L = total axle load (kip)

C12.9.4.4

The results of finite element analyses and field monitoring studies to evaluate the effects of load-induced deformations and in-plane deformed geometries indicate that the design moments should be increased where the cover is less than 3.5 ft.

Eq. 12.9.4.4-1 is discussed in Boulanger et al. (1989).

12.9.4.6—Concrete Relieving Slabs

Relieving slabs may be used to reduce flexural moments in box culverts. Relieving slabs shall not be in contact with the crown as shown in Figure 12.9.4.6-1.

The length of the concrete relieving slab shall be at least 2.0 ft greater than the culvert span and sufficient to project 1.0 ft beyond the haunch on each side of the culvert. The relieving slab shall extend across the width subject to vehicular loading.

The depth of reinforced concrete relieving slabs shall be determined as:

$$t = t_b R_{AL} R_c R_f \quad (12.9.4.6-1)$$

where:

- t = minimum depth of slab (in.)
- t_b = basic slab depth, as specified in Table 12.9.4.6-1 (in.)
- R_{AL} = axle load correction factor, specified in Table 12.9.4.6-2
- R_c = concrete strength correction factor, specified in Table 12.9.4.6-3
- R_f = factor taken as 1.2 for box structures having spans less than 26.0 ft

C12.9.4.6

The box culvert design procedure described herein does not directly incorporate consideration of concrete relieving slabs on the influence of concrete pavement. Therefore, the procedures described in Duncan et al. (1985) should be used instead. At this time, the beneficial effect of a relieving slab can only be determined by refined soil-structure interaction analyses. The provisions given herein are applicable only for box structures having spans under 26.0 ft. The purpose of avoiding contact between the relieving slab and the culvert is to avoid concentration of the load applied through the slab to the crown of the culvert. As little as 1.0- to 3.0-in. clearance is thought to be sufficient to distribute the load.

Where an Owner requires design for an axle other than the standard 32.0-kip axle, the factor, R_{AL} , may be used to adjust the depth of a concrete relieving slab as specified in Eq. 12.9.4.6-1.

Figure 12.9.4.6-1—Metal Box Culverts with Concrete Relieving Slab

Table 12.9.4.6-1—Basic Slab Depth, t_b (in.) (Duncan et al., 1985)

Unified Classification of Subgrade Beneath Slab	Relative Compaction— % of Standard AASHTO Maximum Dry Unit Weight		
	100	95	90
	Basic Slab Depth (in.)		
GW, GP, SW, SP, or SM	7.5	8.0	8.5
SM–SC or SC	8.0	8.5	9.0
ML or CL	8.5	9.0	9.5

3.0	1.19
3.5	1.15
4.0	1.10
4.5	1.05
5.0	1.01
5.5	0.97
6.0	0.94

12.9.5—Construction and Installation

The contract documents shall require that construction and installation conform to Section 26 of the *AASHTO LRFD Bridge Construction Specifications*.

12.10—REINFORCED CONCRETE PIPE**12.10.1—General**

The provisions herein shall apply to the structural design of buried precast reinforced concrete pipes of circular, elliptical, and arch shapes.

C12.10.1

These structures become part of a composite system comprised of the reinforced concrete buried section and the soil envelope.

The structural design of the types of pipes indicated above may proceed by either of two methods:

- The direct design method at the strength limit state as specified in Article 12.10.4.2, or
- The indirect design method at the service limit state as specified in Article 12.10.4.3.

Standard dimensions for these units are shown in AASHTO M 170 and M 170M (ASTM C76 and C76M), AASHTO M 206M/M 206 (ASTM C506M and C506), AASHTO M 207M/M 207 (ASTM C507M and C507), AASHTO M 242M/M 242 (ASTM C655M and C655), and ASTM C1765.

NCHRP 20-07, Task 316 establishes that while direct design for small diameter pipes could lead to more steel reinforcement than when using indirect design, which results from simplifying conservative assumptions during direct design, either design procedure can be employed.

12.10.2—Loading

12.10.2.1—Standard Installations

The contract documents shall specify that the foundation bedding and backfill comply with the provisions of Article 27.5.2 of the *AASHTO LRFD Bridge Construction Specifications*.

Minimum compaction requirements and bedding thickness for standard embankment installations and standard trench installations shall be as specified in Tables 12.10.2.1-1 and 12.10.2.1-2, respectively.

C12.10.2.1

The four standard installations replace the historic bedding classes. A comprehensive soil–structure interaction analysis and design program, SPIDA, was developed and used to perform soil–structure interaction analyses for the various soil and installation parameters encompassed in the provisions. The SPIDA studies used to develop the standard installations were conducted for positive projection embankment conditions to provide conservative results for other embankment and trench conditions. These studies also conservatively assume a hard foundation and bedding existing beneath the invert of the pipe, plus void and/or poorly compacted material in the haunch areas, 15 degrees to 40 degrees each side of the invert, resulting in a load concentration such that calculated moments, thrusts, and shears are increased.

Table 12.10.2.1-1—Standard Embankment Installation Soils and Minimum Compaction Requirements

Installation Type	Bedding Thickness	Haunch and Outer Bedding	Lower Side
Type 1	For soil foundation, use $D_o/24.0$ in. minimum, not less than 3.0 in. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	95% Category I	90% Category I, 95% Category II, or 100% Category III
Type 2—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $D_o/24.0$ in. minimum, not less than 3.0 in. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	90% Category I or 95% Category II	85% Category I, 90% Category II, or 95% Category III
Type 3—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $D_o/24.0$ in. minimum, not less than 3.0 in. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	85% Category I, 90% Category II, or 95% Category III	85% Category I, 90% Category II, or 95% Category III
Type 4	For soil foundation, no bedding required. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	No compaction required, except if Category III, use 85% Category III	No compaction required, except if Category III, use 85% Category III

The following interpretations apply to Table 12.10.2.1-1:

- Compaction and soil symbols (that is, 95 percent Category I) shall be taken to refer to a soil material category with a minimum standard proctor compaction of 95 percent. Equivalent modified proctor values shall be as given in Table 27.5.2.2-3 of the *AASHTO LRFD Bridge Construction Specifications*.
- Soil in the outer bedding, haunch, and lower side zones, except within $B_o/3$ from the pipe springline, shall be compacted to at least the same compaction as the majority of soil in the overfill zone.
- The minimum width of a subtrench shall be $1.33B_o$, or wider if required for adequate space to attain the specified compaction in the haunch and bedding zones.
- For subtrenches with walls of natural soil, any portion of the lower side zone in the subtrench wall shall be at least as firm as an equivalent soil placed to the compaction requirements specified for the lower side zone and as firm as the majority of soil in the overfill zone. Otherwise, it shall be removed and replaced with soil compacted to the specified level.
- A subtrench is defined as a trench in the natural material under an embankment used to retain bedding material with its top below finished grade by more than ten percent of the depth of soil cover on the top of the culvert or pipe. For roadways, the top of a subtrench is at an elevation lower than 1.0 ft below the bottom of the pavement base material.

Table 12.10.2.1-2—Standard Trench Installation Soils and Minimum Compaction Requirements

Installation Type	Bedding Thickness	Haunch and Outer Bedding	Lower Side
Type 1	For soil foundation, use $D_o/24.0$ in. minimum, not less than 3.0 in. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	95% Category I	90% Category I, 95% Category II, or 100% Category III, or natural soils of equal firmness
Type 2—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $D_o/24.0$ in. minimum, not less than 3.0 in. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	90% Category I or 95% Category II	85% Category I, 90% Category II, 95% Category III, or natural soils of equal firmness
Type 3—Installations are available for horizontal elliptical, vertical elliptical, and arch pipe	For soil foundation, use $D_o/24.0$ in. minimum, not less than 3.0 in. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	85% Category I, 90% Category II or 95% Category III	85% Category I, 90% Category II, 95% Category III, or natural soils of equal firmness
Type 4	For soil foundation, no bedding required. For rock foundation, use $D_o/12.0$ in. minimum, not less than 6.0 in.	No compaction required, except if Category III, use 85% Category III	No compaction required except if Category III, use 85% Category III, or natural soil of equal firmness

The following interpretations apply to Table 12.10.2.1-2:

- Compaction and soil symbols (that is, 95 percent Category I) shall be taken to refer to a soil material category with a minimum standard proctor compaction of 95 percent. Equivalent modified proctor values shall be as given in Table 27.5.2.2-3 of the *AASHTO LRFD Bridge Construction Specifications*.

- The trench top elevation shall be no lower than $0.1H$ below finish grade; for roadways, its top shall be no lower than an elevation of 1.0 ft below the bottom of the pavement base material.
- Soil in bedding and haunch zones shall be compacted to at least the same compaction as specified for the majority of soil in the backfill zone.

If required for adequate space to attain the specified compaction in the haunch and bedding zones the trench width shall be wider than that shown in Figures 27.5.2.2-1 and 27.5.2.2-2 of the *AASHTO LRFD Bridge Construction Specifications*.

- For trench walls that are within 10 degrees of vertical, the compaction or firmness of the soil in the trench walls and lower side zone need not be considered.
- For trench walls with greater than 10 degrees slopes that consist of embankment, the lower side shall be compacted to at least the same compaction as specified for the soil in the backfill zone.

The unfactored earth load, W_E , shall be determined as:

$$W_E = F_e w B_c H \quad (12.10.2.1-1)$$

where:

- W_E = unfactored earth load (kip/ft)
 F_e = soil–structure interaction factor for the specified installation, as defined herein
 B_c = out-to-out horizontal dimension of pipe (ft)
 H = height of fill above top of pipe (ft)
 w = unit weight of soil (pcf)

The unit weight of soil used to calculate earth load shall be the estimated unit weight for the soils specified for the pipe soil installation but shall not be taken to be less than 110 lb/ft³.

Standard installations for both embankments and trenches shall be designed for positive projection, embankment loading conditions where F_e shall be taken as the vertical arching factor, VAF , specified in Table 12.10.2.1-3 for each type of standard installation.

For standard installations, the earth pressure distribution shall be the Heger pressure distribution shown in Figure 12.10.2.1-1 and Table 12.10.2.1-3 for each type of standard installation.

The product wB_cH is sometimes referred to as the prism load, PL , the weight of the column of earth over the outside diameter of the pipe.

The earth load for designing pipe using a standard installation is obtained by multiplying the weight of the column of earth above the outside diameter of the pipe by the soil–structure interaction factor, F_e , for the design installation type. F_e accounts for the transfer of some of the overburden soil above the regions at the sides of the pipe because the pipe is more rigid than the soil at the side of the pipe for pipe in embankment and wide trench installations. Because of the difficulty of controlling maximum trench width in the field with the widespread use of trench boxes or sloped walls for construction safety, the potential reduction in earth load for pipe in trenches of moderate to narrow width is not taken into account in the determination of earth load and earth pressure distribution on the pipe. Both trench and embankment installations are to be designed for embankment (positive projecting) loads and pressure distribution in direct design or bedding factors in indirect design.

The earth pressure distribution and lateral earth force for a unit vertical load is the Heger pressure distribution and horizontal arching factor, HAF . The normalized pressure distribution and HAF values were obtained for each standard installation type from the results of soil–structure interaction analyses using SPIDA, together with the minimum soil properties for the soil types and compaction levels specified for the installations.

When nonstandard installations are used, the earth load and pressure distribution should be determined by an appropriate soil–structure interaction analysis.

<i>A4</i>	0.19	0.15	0.10	0.00
<i>A5</i>	0.08	0.08	0.10	0.11
<i>A6</i>	0.18	0.17	0.17	0.19
<i>A</i>	1.40	1.45	1.45	1.45
<i>B</i>	0.40	0.40	0.36	0.30
<i>C</i>	0.18	0.19	0.20	0.25
<i>E</i>	0.08	0.10	0.12	0.00
<i>F</i>	0.05	0.05	0.05	—
<i>U</i>	0.80	0.82	0.85	0.90
<i>V</i>	0.80	0.70	0.60	—

The following shall apply to Table 12.10.2.1-3:

- *VAF* and *HAF* are vertical and horizontal arching factors. These coefficients represent nondimensional total vertical and earth loads on the pipe, respectively. The actual total vertical and horizontal loads are $(VAF) \times (PL)$ and $(HAF) \times (PL)$, respectively, where *PL* is the prism load.

- Coefficients, $A1$ through $A6$, represent the integration of nondimensional vertical and horizontal components of soil pressure under the indicated portions of the component pressure diagrams, i.e., the area under the component pressure diagrams.
- The pressures are assumed to vary either parabolically or linearly, as shown in Figure 12.10.2.1-1, with the nondimensional magnitudes at governing points represented by h_1 , h_2 , uh_1 , vh_2 , a , and b .
- Nondimensional horizontal and vertical dimensions of component pressure regions are defined by c , d , e , uc , vd , and f coefficients,

where:

$$d = (0.5 - c - e) \quad (12.10.2.1-2)$$

$$h_1 = (1.5A1)/(c)(1+u) \quad (12.10.2.1-3)$$

$$h_2 = (1.5A2)/[(d)(1+v) + (2e)] \quad (12.10.2.1-4)$$

12.10.2.2—Pipe Fluid Weight

The unfactored weight of fluid, W_F , in the pipe shall be considered in design based on a fluid weight of 62.4 lb/ft³, unless otherwise specified. For standard installations, the fluid weight shall be supported by vertical earth pressure that is assumed to have the same distribution over the lower part of the pipe as given in Figure 12.10.2.1-1 for earth load.

12.10.2.3—Live Loads

Live loads shall be as specified in Article 3.6 and shall be distributed through the earth cover as specified in Article 3.6.1.2.6. For standard installations, the live load on the pipe shall be assumed to have a uniform vertical distribution across the top of the pipe and the same distribution across the bottom of the pipe as given in Figure 12.10.2.1-1.

12.10.3—Service Limit State

The width of cracks in the wall shall be investigated at the service limit state for moment and thrust. Generally, the crack width should not exceed 0.01 in.

12.10.4—Safety Against Structural Failure

12.10.4.1—General

The resistance of buried reinforced concrete pipe structures against structural failure shall be determined at the strength limit state for:

- Flexure,
- Thrust,
- Shear, and
- Radial tension.

The dimensions of pipe sections shall be determined using either the analytically-based direct design method or the empirically based indirect design method.

When quadrant mats, stirrups, and/or elliptical cages are specified in the contract documents, the orientation of the pipe installation shall be specified, and the design shall account for the possibility of an angular misorientation of 10 degrees during the pipe installation.

12.10.4.2—Direct Design Method

12.10.4.2.1—Loads and Pressure Distribution

The total vertical load acting on the pipe shall be determined as specified in Article 12.10.2.1.

The pressure distribution on the pipe from applied loads and bedding reaction shall be determined from either a soil-structure analysis or from a rational approximation, either of which shall permit the development of a pressure diagram, shown schematically in Figure 12.10.4.2.1-1, and the analysis of the pipe.

C12.10.4.1

The direct design method uses a pressure distribution on the pipe from applied loads and bedding reactions based on a soil-structure interaction analysis or an elastic approximation. The indirect design method uses empirically-determined bedding factors that relate the total factored earth load to the concentrated loads and reactions applied in three-edge bearing tests.

C12.10.4.2.1

The direct design method was accepted in 1993 by ASCE and is published in ASCE 93-15, *Standard Practice for Direct Design of Buried Precast Concrete Pipe Using Standard Installations* (SIDD). The design method was developed along with the research performed on the standard installations. However, the design equations are applied after the required flexural moments, thrusts, and shear forces at all critical sections have been determined using any one of the acceptable pressure distributions. Therefore, the use of the design equations herein is not limited to the standard installations or any one assumed pressure distribution.

Direct design requires:

- The determination of earth loads and live load pressure distributions on the structure for the bedding and installation conditions selected by the Engineer;
- Analysis to determine thrust, moments, and shears; and
- Design to determine circumferential reinforcement.

The procedures for analysis and design are similar to those used for other reinforced concrete structures.

Figure 12.10.4.2.1-1—Suggested Design Pressure Distribution around a Buried Concrete Pipe for Analysis by Direct Design

12.10.4.2.2—Analysis for Force Effects with the Pipe Ring

Force effects in the pipe shall be determined by an elastic analysis of the pipe ring under the assumed pressure distribution or a soil-structure analysis.

If thin ring theory is employed, the expected moments at crown and invert can be adjusted to account for ring thickness by:

$$M_{thick} = M_{thin} \left(1 - 0.373 \frac{t}{R} \right) \quad (12.10.4.2.2-1)$$

where:

M_{thick}	=	adjusted moment
M_{thin}	=	moment calculated using thin ring theory
t	=	thickness of the concrete pipe
R	=	average radius of the concrete pipe

12.10.4.2.3—Process and Material Factors

Process and material factors, F_{rp} for radial tension and F_{vp} for shear strength, for design of plant-made reinforced concrete pipe should be taken as 1.0. Higher values of these factors may be used if substantiated by sufficient testing in accordance with AASHTO M 242M/M 242 (ASTM C655M and C655).

12.10.4.2.4—Flexural Resistance at the Strength Limit State

12.10.4.2.4a—Circumferential Reinforcement

Reinforcement for flexural resistance provided in a length, b , usually taken as 12.0 in., shall satisfy:

$$A_y \geq \frac{g\phi d - N_u - \sqrt{g \left[g(\phi d)^2 - N_u(2\phi d - h) - 2M_u \right]}}{f_y} \quad (12.10.4.2.4a-1)$$

in which:

$$g = 0.85bf'_c \quad (12.10.4.2.4a-2)$$

where:

A_s = area of reinforcement per length of pipe, b
(in.²/ft)
 f_y = specified yield strength of reinforcing less than
or equal to 80 ksi
 d = distance from compression face to centroid of
tension reinforcement (in.)
 h = wall thickness of pipe (in.)
 M_u = moment due to factored loads (kip-in./ft)

C12.10.4.2.2

NCHRP 20-07, Task 316 establishes that the discrepancies in quantities of flexural reinforcement resulting from direct and indirect design are partly due to the use of thin ring theory. Adjustment to account for thick ring theory resolves those discrepancies in part, though much of the conservatism of direct design remains (for example, the estimation of expected moment and consideration of ultimate limit state based on first plastic moment).

C12.10.4.2.4a

NCHRP 20-07, Task 316 establishes that more sophisticated procedures can be employed for estimating the flexural and shear resistance at the strength limit state, such as Modified Compression Field Theory, to enforce compatibility between steel and concrete components and account for multiple layers of steel reinforcement and nonlinear concrete and steel behavior.

The required area of steel, A_s , as determined by Eq. 12.10.4.2.4a-1, should be distributed over a unit length of the pipe, b , which is typically taken as 12.0 in.

The factored actions should also be consistent with the selected unit width.

- N_u = thrust due to factored load, taken to be positive for compression (kip/ft)
- ϕ = resistance factor for flexure, specified in Article 12.5.5

12.10.4.2.4b—Minimum Reinforcement

The reinforcement, A_s , per ft of pipe shall not be less than:

- For inside face of pipe with two layers of reinforcement:

$$A_s \geq \frac{(S_i + h)^2}{1,000 f_y} \geq 0.07 \quad (12.10.4.2.4b-1)$$

- For outside face of pipe with two layers of reinforcement:

$$A_s \geq 0.60 \frac{(S_i + h)^2}{1,000 f_y} \geq 0.07 \quad (12.10.4.2.4b-2)$$

- For elliptical reinforcement in circular pipe and for 33.0-in. diameter and smaller pipe with a single cage of reinforcement in the middle third of the pipe wall:

$$A_s \geq 2 \frac{(S_i + h)^2}{1,000 f_y} \geq 0.07 \quad (12.10.4.2.4b-3)$$

where:

- S_i = internal diameter or horizontal span of the pipe (in.)
- h = wall thickness of pipe (in.)
- f_y = yield strength of reinforcement less than or equal to 80 ksi

12.10.4.2.4c—Maximum Flexural Reinforcement without Stirrups

C12.10.4.2.4c

The flexural reinforcement per foot of pipe without stirrups shall satisfy:

- For inside steel in radial tension:

$$A_{smax} \leq \frac{0.506 r_s F_{rp} \sqrt{f'_c} (R_\phi) F_{rt}}{f_y} \quad (12.10.4.2.4c-1)$$

where:

- A_{smax} = minimum flexural reinforcement area without stirrups (in.²/ft)
- r_s = radius of the inside reinforcement (in.)
- f'_c = compressive strength of concrete (ksi)
- f_y = specified yield strength of reinforcement less than or equal to 80 ksi

Research has shown that reinforcing steel with yield strengths up to 80 ksi can be used in the flexural design of concrete. Eqs. 12.10.4.2.4c-1 and 12.10.4.2.4c-2 utilize the reinforcing yield stress times the area of reinforcement to establish a tension force applied to the concrete. Higher reinforcing yield strengths will result in higher tension forces for an equivalent area of steel. Thus, the allowable maximum steel area is less when utilizing high strength reinforcement. Therefore, the same reinforcing yield strength value used in determining the flexural reinforcement area in Eq. 12.10.4.2.4a-1 should be used in Eqs. 12.10.4.2.4c-1 and 12.10.4.2.4c-2.

in which:

$$j = 0.74 + 0.1 \frac{e}{d} \leq 0.9 \quad (12.10.4.2.4d-3)$$

$$i = \frac{1}{\left(1 - \frac{jd}{e}\right)} \quad (12.10.4.2.4d-4)$$

$$e = \frac{M_s}{N_s} + d - \frac{h}{2} \quad (12.10.4.2.4d-5)$$

$$B_1 = \left(\frac{t_b S_\ell}{2n} \right)^{\frac{1}{3}} \quad (12.10.4.2.4d-6)$$

where:

M_s = flexural moment at service limit state (kip-in./ft)

N_s = axial thrust at service limit state (kip/ft)

d = distance from compression face to centroid of tension reinforcement (in.)

h = wall thickness (in.)

f'_c = specified compressive strength of concrete (ksi)

C_1 = crack control coefficient for various types of reinforcement, as specified in Table 12.10.4.2.4d-1

A_s = area of steel (in.²/ft)

i = coefficient for effect of axial force at service limit state, f_s

j = coefficient for moment arm at service limit state, f_s

b = width of section taken as 12.0 in.

t_b = clear cover over reinforcement (in.)

S_ℓ = spacing of circumferential reinforcement (in.)

n = 1.0 when tension reinforcement is a single layer

n = 2.0 when tension reinforcement is made of multiple layers

ϕ = resistance factor for flexure, as specified in Article 12.5.5

Table 12.10.4.2.4d-1—Crack Control Coefficients

Type	Reinforcement	C_1
1	Smooth wire or plain bars	1.0
2	Welded smooth wire fabric with 8.0-in. maximum spacing of longitudinals, welded deformed wire fabric, or deformed wire	1.5
3	Deformed bars or any reinforcement with stirrups anchored thereto	1.9

For Type 2 reinforcement in Table 12.10.4.2.4d-1 having $t_b^2 S/n > 3.0$, the crack width factor, F_{cr} , shall also be investigated using coefficients B_1 and C_1 specified for Type 3 reinforcement, and the larger value for F_{cr} shall be used.

Higher values for C_1 may be used if substantiated by test data and approved by the Engineer.

12.10.4.2.4e—Minimum Concrete Cover

The provisions of Article 5.10.1 shall apply to minimum concrete cover, except as follows:

- If the wall thickness is less than 2.5 in., the cover shall not be less than 0.75 in., and
- If the wall thickness is not less than 2.5 in., the cover shall not be less than 1.0 in.

12.10.4.2.5—Shear Resistance without Stirrups

C12.10.4.2.5

The section shall be investigated for shear at a critical section taken where $M_{nu}/(V_u d) = 3.0$. The factored shear resistance without radial stirrups, V_r , shall be taken as:

$$V_r = \phi V_n \quad (12.10.4.2.5-1)$$

in which:

$$V_n = 0.0316 b d F_{yp} \sqrt{f'_c} (1.1 + 63\rho) \left(\frac{F_d F_n}{F_c} \right) \quad (12.10.4.2.5-2)$$

$$\rho = \frac{A_s}{b d} \leq 0.02 \quad (12.10.4.2.5-3)$$

- For pipes with two cages or a single elliptical cage:

$$F_d = 0.8 + \frac{1.6}{d} \leq 1.3 \quad (12.10.4.2.5-4)$$

- For pipes not exceeding 36.0-in. diameter with a single circular cage:

$$F_d = 0.8 + \frac{1.6}{d} \leq 1.4 \quad (12.10.4.2.5-5)$$

If N_u is compressive, it is taken as positive and:

$$F_n = 1 + \frac{N_u}{24h} \quad (12.10.4.2.5-6)$$

If N_u is tensile, it is taken as negative and:

$$F_n = 1 + \frac{N_u}{6h} \quad (12.10.4.2.5-7)$$

Where $F_{cr} = 1.0$, the specified reinforcement is expected to produce an average maximum crack width of 0.01 in. For $F_{cr} < 1.0$, the probability of a 0.01-in. crack is reduced, and for $F_{cr} > 1.0$, it is increased.

For the purpose of this Article, a cage is considered to be a layer of reinforcement.

$$F_c = 1 \pm \frac{d}{2r} \quad (12.10.4.2.5-8)$$

$$M_{nu} = M_u - N_u \left[\frac{(4h-d)}{8} \right] \quad (12.10.4.2.5-9)$$

The algebraic sign in Eq. 12.10.4.2.5-8 shall be taken as positive where tension is on the inside of the pipe and negative where tension is on the outside of the pipe.

where:

- f'_{cmax} = 7.0 ksi
- b = width of design section, taken as 12.0 in.
- d = distance from compression face to centroid of tension reinforcement (in.)
- h = wall thickness (in.)
- ϕ = resistance factor for shear, as specified in Article 5.5.4.2
- r = radius to centerline of concrete pipe wall (in.)
- N_u = thrust due to factored loads (kip/ft)
- V_u = shear due to factored loads (kip/ft)
- F_{vp} = process and material factor, specified in Article 12.10.4.2.3

If the factored shear resistance, as determined herein, is not adequate, radial stirrups shall be provided in accordance with Article 12.10.4.2.6.

12.10.4.2.6—Shear Resistance with Radial Stirrups

Radial tension and shear stirrup reinforcement shall not be less than:

- For radial tension:

$$A_{vr} = \frac{1.1s_v(M_u - 0.45N_u\phi_r d)}{f_y r_s \phi_r d} \quad (12.10.4.2.6-1)$$

$$s_v \leq 0.75\phi_r d \quad (12.10.4.2.6-2)$$

- For shear:

$$A_{vs} = \frac{1.1s_v}{f_y \phi_v d} (V_u F_c - V_c) + A_{vr} \quad (12.10.4.2.6-3)$$

$$s_v \leq 0.75\phi_v d \quad (12.10.4.2.6-4)$$

in which:

$$V_c = \frac{4V_u}{\frac{M_{nu}}{V_u d} + 1} \leq 0.0633\phi_v b d \sqrt{f'_c} \quad (12.10.4.2.6-5)$$

where:

- | | | |
|----------|---|--|
| M_u | = | flexural moment due to factored loads (kip-in./ft) |
| M_{nu} | = | factored moment acting on cross-section width, b , as modified for effects of compressive or tensile thrust (kip-in./ft) |
| N_u | = | thrust due to factored loads (kip/ft) |
| V_u | = | shear due to factored loads (kip/ft) |
| V_c | = | shear resistance of concrete section (kip/ft) |
| d | = | distance from compression face to centroid of tension reinforcement (in.) |
| f_y | = | specified yield strength for reinforcement; the value of f_y shall be taken as the lesser of the yield strength of the stirrup or its developed anchorage capacity (ksi) |
| r_s | = | radius of inside reinforcement (in.) |
| s_v | = | spacing of stirrups (in.) |
| V_r | = | factored shear resistance of pipe section without radial stirrups per unit length of pipe (kip/ft) |
| A_{vr} | = | stirrup reinforcement area to resist radial tension forces on cross-section width, b , in each line of stirrups at circumferential spacing, s_v (in. ² /ft) |
| A_{vs} | = | required area of stirrups for shear reinforcement (in. ² /ft) |
| f'_c | = | compressive strength of concrete (ksi) |
| ϕ_v | = | resistance factor for shear, as specified in Article 12.5.5 |
| ϕ_r | = | resistance factor for radial tension, as specified in Article 12.5.5 |
| F_c | = | curvature factor, as determined by Eq. 12.10.4.2.5-8 |

12.10.4.2.7—Stirrup Reinforcement Anchorage

12.10.4.2.7a—Radial Tension Stirrup Anchorage

When stirrups are used to resist radial tension, they shall be anchored around each circumferential of the inside cage to develop the resistance of the stirrup, and they shall also be anchored around the outside cage or embedded sufficiently in the compression side to develop the required resistance of the stirrup.

C12.10.4.2.7a

Stirrup reinforcement anchorage development research by pipe manufacturers has demonstrated that the free ends of loop-type stirrups need only be anchored in the compression zone of the concrete cross-section to develop the full tensile strength of the stirrup wire. Stirrup loop lengths equivalent to 70 percent of the wall thickness may be considered to provide adequate anchorage.

12.10.4.2.7b—Shear Stirrup Anchorage

Except as specified herein, when stirrups are not required for radial tension but required for shear, their longitudinal spacing shall be such that they are anchored around each tension circumferential or every other tension circumferential. The spacing of such stirrups shall not exceed 6.0 in.

12.10.4.2.7c—Stirrup Embedment

Stirrups intended to resist forces in the invert and crown regions shall be anchored sufficiently in the opposite side of the pipe wall to develop the required resistance of the stirrup.

12.10.4.3—Indirect Design Method

12.10.4.3.1—Bearing Resistance

Earth and live loads on the pipe shall be determined in accordance with Article 12.10.2 and compared to three-edge bearing strength D-load for the pipe. The service limit state shall apply using the criterion of acceptable crack width specified herein.

The D-load for a particular class and size of pipe shall be determined in accordance with AASHTO M 170M and M 170 (ASTM C76M and C76), M 206M/M 206 (ASTM C506M and C506), M 207M/M 207 (ASTM C507M and C507), M 242M/M 242 (ASTM C655M and C655), or ASTM C1765.

The three-edge bearing resistance of the reinforced concrete pipe, corresponding to an experimentally tested service load, shall not be less than the design load determined for the pipe as installed, taken as:

$$D = \left(\frac{12}{S_i} \right) \left(\frac{W_E + W_F}{B_{FE}} + \frac{W_L}{B_{FLL}} \right) \quad (12.10.4.3.1-1)$$

where:

- B_{FE} = earth load bedding factor, specified in Article 12.10.4.3.2a or Article 12.10.4.3.2b
- B_{FLL} = live load bedding factor, specified in Article 12.10.4.3.2c
- S_i = internal diameter of pipe (in.)
- W_E = total unfactored earth load, specified in Article 12.10.2.1 (kip/ft)
- W_F = total unfactored fluid load in the pipe, as specified in Article 12.10.2.2 (kip/ft)
- W_L = total unfactored live load on unit length pipe, specified in Article 12.10.2.3 (kip/ft)

For Type 1 installations, D loads, as calculated above, shall be modified by multiplying by an installation factor of 1.10.

12.10.4.3.2—Bedding Factor

The minimum compaction specified in Tables 12.10.2.1-1 and 12.10.2.1-2 shall be required by the contract document.

C12.10.4.3.1

The indirect design method has been the most commonly utilized method of design for buried reinforced concrete pipe. It is based on correlating the stress on the pipe in the field to the stress on the pipe when tested in the three-edge bearing apparatus.

The required D-load at which the pipe develops its ultimate strength in a three-edge bearing test is the design D-load at service, as calculated in Eq. 12.10.4.3.1-1, multiplied by a strength factor specified in the manufacturing standard. For conventionally reinforced concrete pipe produced to AASHTO M 170M and M 170 (ASTM C76M and C76), M 242M/M 242 (ASTM C655M and C655), M 206M/M 206 (ASTM C506M and C506) or M 207M/M 207 (ASTM C507M and C507) the service load criteria in the three-edge bearing test is a 0.01-in. crack. For fiber reinforced concrete pipe produced to ASTM C1765, a 0.01-in. crack is not reached at the design service load. Thus, the pipes are tested to ultimate strength in the three-edge bearing test.

C12.10.4.3.2

The bedding factor is the ratio of the moment at service limit state to the moment applied in the three-edge bearing test. The standard supporting strength of buried pipe depends on the type of installation. The bedding factors given herein are based on the minimum levels of compaction indicated.

12.10.4.3.2a—Earth Load Bedding Factor for
Circular Pipe

C12.10.4.3.2a

Earth load bedding factors, B_{FE} , for circular pipe are presented in Table 12.10.4.3.2a-1.

For pipe diameters, other than those listed in Table 12.10.4.3.2a-1, embankment condition bedding factors, B_{FE} , may be determined by interpolation.

The bedding factors for circular pipe were developed using the flexural moments produced by the Heger pressure distributions from Figure 12.10.2.1-1 for each of the standard embankment installations. The bedding factors for the embankment condition are conservative for each installation. This conservatism is based on assuming voids and poor compaction in the haunch areas and a hard bedding beneath the pipe in determining the moments, thrusts, and shears used to calculate the bedding factors. The modeling of the soil pressure distribution used to determine moments, thrusts, and shears is also conservative by 10–20 percent, compared with the actual SPIDA analysis.

Table 12.10.4.3.2a-1—Bedding Factors for Circular Pipe

Pipe Diameter, in.	Standard Installations			
	Type 1	Type 2	Type 3	Type 4
12	4.4	3.2	2.5	1.7
24	4.2	3.0	2.4	1.7
36	4.0	2.9	2.3	1.7
72	3.8	2.8	2.2	1.7
144	3.6	2.8	2.2	1.7

12.10.4.3.2b—Earth Load Bedding Factor for
Arch and Elliptical Pipe

The bedding factor for installation of arch and elliptical pipe shall be taken as:

$$B_{FE} = \frac{C_A}{C_N - xq} \quad (12.10.4.3.2b-1)$$

where:

- C_A = constant corresponding to the shape of the pipe, as specified in Table 12.10.4.3.2b-1
- C_N = parameter that is a function of the distribution of the vertical load and vertical reaction, as specified in Table 12.10.4.3.2b-1
- x = parameter that is a function of the area of the vertical projection of the pipe over which lateral pressure is effective, as specified in Table 12.10.4.3.2b-1
- q = ratio of the total lateral pressure to the total vertical fill load specified herein

Design values for C_A , C_N , and x are listed in Table 12.10.4.3.2b-1.

Table 12.10.4.3.2b-1—Design Values of Parameters in Bedding Factor Equation

Pipe Shape	C_A	Installation Type	C_N	Projection Ratio, p	x
Horizontal Elliptical and Arch	1.337	2	0.630	0.9	0.421
				0.7	0.369
		3	0.763	0.5	0.268
				0.3	0.148
Vertical Elliptical	1.021	2	0.516	0.9	0.718
				0.7	0.639
		3	0.615	0.5	0.457
				0.3	0.238

The value of the parameter, q , is taken as:

- For arch and horizontal elliptical pipe:

$$q = 0.23 \frac{p}{F_e} \left(1 + 0.35 p \frac{B_c}{H} \right) \quad (12.10.4.3.2b-2)$$

- For vertical elliptical pipe:

$$q = 0.48 \frac{p}{F_e} \left(1 + 0.73 p \frac{B_c}{H} \right) \quad (12.10.4.3.2b-3)$$

where:

p = projection ratio, ratio of the vertical distance between the outside top of the pipe and the ground of bedding surface to the outside vertical height of the pipe

12.10.4.3.2c—Live Load Bedding Factors

The bedding factor, B_{FLL} , for live load, W_L , for both circular pipe and arch and for elliptical pipe shall be taken as specified in Table 12.10.4.3.2c-1. For pipe diameters not listed in Table 12.10.4.3.2c-1, the bedding factor may be determined by interpolation.

Table 12.10.4.3.2c-1—Bedding Factors, B_{FLL}

Pipe diameter, in.	Fill Height, ft	
	< 2.0 ft	≥ 2.0 ft
12	3.2	2.4
18	3.2	2.4
24	3.2	2.4
30 and larger	2.2	2.2

12.10.4.3.2c

The relatively large bending stiffness in the longitudinal direction of concrete pipe results in the distribution of the live load force along the length of the pipe. This ratio of distribution length to pipe diameter is higher in small diameter pipes designed by the Indirect Design Method. The bedding factor has been adjusted in Table 12.10.4.3.2c-1 to account for this higher distribution length.

12.10.4.4—Development of Quadrant Mat Reinforcement

12.10.4.4.1—Minimum Cage Reinforcement

In lieu of a detailed analysis, when quadrant mat reinforcement is used, the area of the main cage shall be

12.10.5—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 27 of the *AASHTO LRFD Bridge Construction Specifications*.

12.11—REINFORCED CONCRETE CAST-IN-PLACE AND PRECAST BOX CULVERTS AND REINFORCED CAST-IN-PLACE ARCHES

12.11.1—General

The provisions herein shall apply to the structural design of cast-in-place and precast reinforced concrete box culverts and cast-in-place reinforced concrete arches with the arch barrel monolithic with each footing.

Designs shall conform to applicable Articles of these Specifications, except as provided otherwise herein.

12.11.2—Loads and Live Load Distribution

12.11.2.1—General

Loads and load combinations specified in Table 3.4.1-1 shall apply. Live load shall be considered as specified in Article 3.6.1.3. Distribution of wheel loads and concentrated loads for culverts with less than 2.0 ft of fill shall be taken as specified in Article 4.6.2.10. For traffic traveling parallel to the span, box culverts shall be designed for a single loaded lane with the single lane multiple presence factor applied to the load. Requirements for bottom distribution reinforcement in top slabs of such culverts shall be as specified in Article 9.7.3.2 for mild steel reinforcement and Article 5.12.2.1 for prestressed reinforcement.

Distribution of wheel loads to culverts with 2.0 ft or more of cover shall be as specified in Article 3.6.1.2.6.

The dynamic load allowance for buried structures shall conform to Article 3.6.2.2.

For cast-in-place box culverts, and for precast box culverts with top slabs having span-to-thickness ratios (s/t) >18 or segment lengths <4.0 ft, edge beams shall be provided as specified in Article 4.6.2.1.4 as follows:

- At ends of culvert runs where wheel loads travel within 24.0 in. from the end of culvert,
- At expansion joints of cast-in-place culverts where wheel loads travel over or adjacent to the expansion joint.

C12.11.1

These structures become part of a composite system comprised of the box or arch culvert structure and the soil envelope.

Precast reinforced concrete box culverts may be manufactured using conventional structural concrete and forms, or they may be machine made with dry concrete and vibrating form pipe making methods.

Standard dimensions for precast reinforced concrete box culverts are shown in AASHTO M 259 (ASTM C789) and AASHTO M 273 (ASTM C850).

C12.11.2.1

For the design of box culverts, three general load combinations envelope all controlling force effects for the Strength and Service limit states. These are:

- Maximum vertical, Maximum horizontal
- Maximum vertical, Minimum horizontal
- Minimum vertical, Maximum horizontal

Controlling force effects with maximum horizontal loads may occur with live load surcharge (LS) present or absent. Both situations should be investigated.

Research into live load distribution on box culverts (McGrath et al., 2004) has shown that design for a single loaded lane with a multiple presence factor of 1.2 on the live load and using the live load distribution widths in Article 4.6.2.10 will provide adequate design loading for multiple loaded lanes with multiple presence factors of 1.0 or less when the traffic direction is parallel to the span.

The edge beam provisions are only applicable for culverts with less than 2.0 ft of fill. Precast box culverts with span-to-thickness ratios (s/t) ≤ 18 have been shown to have significantly more strength than would be predicted by Article 5.7.3 (Garg et al., 2007) (Abolmaali and Garg, 2008a; 2008b). While the distribution of the load when it is applied to the edge of these structures would not be as large as would be predicted by Article 4.6.2.10, the residual strength in the structure more than compensates for the liberal load distribution.

12.11.2.2—Modification of Earth Loads for Soil–Structure Interaction

12.11.2.2.1—Embankment and Trench Conditions

In lieu of a more refined analysis, the total unfactored earth load, W_E , acting on the culvert may be taken as:

- For embankment installations:

$$W_E = F_e \gamma_s B_c H \quad (12.11.2.2.1-1)$$

in which:

$$F_e = 1 + 0.20 \frac{H}{B_c} \quad (12.11.2.2.1-2)$$

- For trench installations:

$$W_E = F_t \gamma_s B_c H \quad (12.11.2.2.1-3)$$

in which:

$$F_t = \frac{C_d B_d^2}{H B_c} \leq F_e \quad (12.11.2.2.1-4)$$

where:

- W_E = total unfactored earth load (kip/ft)
- B_c = outside width of culvert, as specified in Figures 12.11.2.2.1-1 or 12.11.2.2.1-2, as appropriate (ft)
- H = height of backfill, as specified in Figures 12.11.2.2.1-1 or 12.11.2.2.1-2 (ft)
- F_e = soil–structure interaction factor for embankment installation, specified herein
- F_t = soil–structure interaction factor for trench installations, specified herein
- γ_s = unit weight of backfill (kcf)
- B_d = horizontal width of trench, as specified in Figure 12.11.2.2.1-2 (ft)
- C_d = a coefficient, specified in Figure 12.11.2.2.1-3

F_e shall not exceed 1.15 for installations with compacted fill along the sides of the box section, or 1.40 for installations with uncompacted fill along the sides of the box section.

For wide trench installations where the trench width exceeds the horizontal dimension of the culvert across the trench by more than 1.0 ft, F_t shall not exceed the value specified for an embankment installation.

EMBANKMENT CONDITION

Figure 12.11.2.2.1-1—Embankment Condition—Precast Concrete Box Sections

TRENCH CONDITION

Figure 12.11.2.2.1-2—Trench Condition—Precast Concrete Box Sections

Figure 12.11.2.2.1-3—Coefficient, C_d , for Trench Installations

12.11.2.2.2—Other Installations

Methods of installation other than embankment or trench may be used to reduce the loads on the culvert, including partial positive projection, 0.0 projection, negative projection, induced trench, and jacked installations. The loads for such installations may be determined by accepted methods based on tests, soil-structure interaction analyses, or previous experience.

12.11.2.3—Distribution of Concentrated Loads to Bottom Slab of Box Culvert

The width of the top slab strip used for distribution of concentrated wheel loads, specified in Article 12.11.2, shall also be used for the determination of moments, shears, and thrusts in the side walls and the bottom slab.

C12.11.2.3

Restricting the live load distribution width for the bottom slab to the same width used for the top slab provides designs suitable for multiple loaded lanes, even though analysis is only completed for a single loaded lane (as discussed in Article C12.11.2.1).

While typical designs assume a uniform pressure distribution across the bottom slab, a refined analysis that considers the actual soil stiffness under box sections will result in pressure distributions that reduce bottom slab shear and moment forces (McGrath et al., 2004).

Such an analysis requires knowledge of in-situ soil properties to select the appropriate stiffness for the supporting soil. A refined analysis taking this into account may be beneficial when analyzing existing culverts.

12.11.2.4—Distribution of Concentrated Loads in Skewed Box Culverts

Wheel distribution specified in Article 12.11.2.3 need not be corrected for skew effects.

12.11.3—Strength Limit State

The provisions of Article 12.10.4.2.4a may be applied to the flexural strength design of slabs and walls of reinforced concrete cast-in-place and precast box culverts and reinforced cast-in-place arches.

12.11.4—Service Limit State

The provisions of Article 5.6.7 shall apply to crack width control in reinforced concrete cast-in-place and precast box culverts and reinforced cast-in-place arches.

C12.11.3

Buried structures may be subject to high compressive thrust forces compared to most flexural members, and this thrust can result in a reduction in the required steel area. While influential in the reinforcement design, these thrust forces are not significant enough to warrant an individual analysis of compressive forces and flexural moments separately. Thus, Eq. 12.10.4.2.4a-1 may be used as a simplified, yet direct, method of determining the reinforcement areas for these structures.

C12.11.4

Although high compressive thrust forces are usually considered in strength design, they are often ignored in service limit state design. The following equations, derived from ACI SP-3, can be used to consider the effect of thrust on stresses at the service limit state:

$$f_s = \frac{M_s + N_s \left(d - \frac{h}{2} \right)}{(A_s j d)} \quad (\text{C12.11.4-1})$$

in which:

$$\begin{aligned} e &= M_s / N_s + d - h / 2 \\ i &= 1 / (1 - j d / e) \\ j &= 0.74 + 0.1(e / d) \leq 0.9 \end{aligned}$$

where:

M_s	=	flexural moment at service limit state (kip-in./ft)
N_s	=	axial thrust at service limit state (kip/ft)
d	=	distance from compression face to centroid of tension reinforcement (in.)
h	=	wall thickness (in.)
A_s	=	area of reinforcement per unit length (in. ² /ft)
f_s	=	reinforcement stress under service load condition (ksi)
e/d min	=	1.15 (dim.)

i = coefficient for effect of axial force at service limit state, f_s
 j = coefficient for moment arm at service limit state, f_s

12.11.5—Safety Against Structural Failure

12.11.5.1—General

All sections shall be designed for the applicable factored loads specified in Table 3.4.1-1 at the strength limit state, except as modified herein. Shear in culverts shall be investigated in conformance with Article 5.12.7.3.

12.11.5.2—Design Moment for Box Culverts

Where monolithic haunches inclined at 45 degrees are specified, negative reinforcement in walls and slabs may be proportioned based on the flexural moment at the intersection of the haunch and uniform depth member. Otherwise, the provisions of Section 5 shall apply.

12.11.5.3—Minimum Reinforcement

12.11.5.3.1—Cast-in-Place Structures

Reinforcement shall not be less than that specified in Article 5.6.3.3 at all cross-sections subject to flexural tension, including the inside face of walls. Shrinkage and temperature reinforcement shall be provided near the inside surfaces of walls and slabs in accordance with Article 5.10.6.

12.11.5.3.2—Precast Box Structures

At all box culvert cross-sections subjected to flexural tension, the minimum reinforcement area shall be not less than 0.002 times the gross concrete area.

For top slabs of box culverts having less than 2.0 ft of cover, the bottom longitudinal reinforcement area shall be the greater of the distribution reinforcement required per Article 9.7.3.2 or 0.002 times the gross concrete area.

For all other longitudinal reinforcement, the minimum longitudinal reinforcement area shall not be less than 0.03 in.²/ft at each face.

Where the fabricated length exceeds 16.0 ft, the minimum reinforcement shall also meet the requirements of Article 5.10.6.

C12.11.5.3.2

The minimum requirement pertains to all reinforcement parallel to the span or rise on the inside and outside faces in walls and slabs of box culverts.

Designers suggested a minimum amount of reinforcement in consideration of handling, placement, backfilling, settlement, and long-term service life. For box culvert cross-sections subjected to flexural tension under typical in-service conditions, a ratio of reinforcement to gross concrete area of 0.002 is considered sufficient. Results from research performed on precast boxes at the University of Texas at Arlington showed no flexural tension in the direction perpendicular to the span of the box for wheel loads applied at the edge of a culvert segment. However, to protect the box culvert during the conditions listed above, some longitudinal steel is recommended. A minimum longitudinal reinforcement area of 0.03 in.²/ft at each face is considered adequate to meet these needs. This minimum requirement may be at least partially satisfied by the transverse wires when wire mesh reinforcement is used.

12.11.5.4—Minimum Cover for Precast Box Structures

The provisions of Article 5.10.1 shall apply.

12.11.6—Construction and Installation

The contract documents shall require that construction and installation conform to Section 27 of the *AASHTO LRFD Bridge Construction Specifications*.

12.12—THERMOPLASTIC PIPES

12.12.1—General

The provisions herein shall apply to the structural design of buried thermoplastic pipe with solid, corrugated, or profile wall, manufactured of PE, PP, or PVC.

C12.12.1

These structures become part of a composite system comprised of the plastic pipe and the soil envelope.

The following specifications are applicable:

For PE:

- Solid Wall—ASTM F714,
- Corrugated—AASHTO M 294, and
- Profile—ASTM F894.

For PP:

- Corrugated—AASHTO M 330

For PVC:

- Solid Wall—AASHTO M 278 and
- Profile—AASHTO M 304.

12.12.2—Service Limit States

12.12.2.1—General

The allowable maximum localized distortion of installed plastic pipe shall be limited based on the service requirements of the installation. The extreme fiber tensile strain shall not exceed the allowable long-term strain in Table 12.12.3.3-1. The net tension strain shall be the numerical difference between the bending tensile strain and ring compression strain.

C12.12.2.1

The allowable long-term strains should not be reached in pipes designed and constructed in accordance with these Specifications. Deflections resulting from conditions imposed during pipe installation should also be considered in design.

12.12.2.2—Deflection Requirement

Total deflection, Δ_t , shall be less than the allowable deflection, Δ_A , as follows:

$$\Delta_t \leq \Delta_A \quad (12.12.2.2-1)$$

where:

Δ_t = total deflection of pipe expressed as a reduction of the vertical diameter taken as positive for

C12.12.2.2

Deflection is controlled through proper construction in the field, and construction contracts should place responsibility for control of deflections on the contractor. However, feasibility of a specified installation needs to be checked prior to writing the project specifications.

The construction specifications set the allowable deflection, Δ_A , for thermoplastic pipe at five percent as a generally appropriate limit. The Engineer may allow alternate deflection limits for specific projects if

reduction of the vertical diameter and expansion of horizontal diameter. (in.)

Δ_A = total allowable deflection of pipe, reduction of vertical diameter (in.)

Total deflection, calculated using Spangler's expression for predicting flexural deflection in combination with the expression for circumferential shortening, shall be determined as:

$$\Delta_t = \frac{K_B (D_L P_{sp} + C_L P_L) D_o}{1000 (E_p I_p / R^3 + 0.061 M_s)} + \epsilon_{sc} D \quad (12.12.2.2-2)$$

where:

ϵ_{sc} = service compressive strain, as specified in Article 12.12.3.10.1c

D_L = deflection lag factor, a value of 1.5 is typical

K_B = bedding coefficient, a value of 0.10 is typical

P_{sp} = soil prism pressure evaluated at pipe springline, as specified in Article 12.12.3.7 (psi)

C_L = live load coefficient, as specified in Article 12.12.3.5

P_L = live load pressure, as specified in Article 3.6.1.2.6

D_o = outside diameter of pipe (in.), as shown in Figure C12.12.2.2-1

E_p = short- or long-term modulus of pipe material, as specified in Table 12.12.3.3-1 (ksi)

I_p = moment of inertia of pipe profile per unit length of pipe (in.⁴/in.)

R = radius from center of pipe to centroid of pipe profile (in.), as shown in Figure C12.12.2.2-1

D = diameter to centroid of pipe profile (in.), as shown in Figure C12.12.2.2-1

M_s = secant constrained soil modulus, as specified in Article 12.12.3.5 (ksi)

calculations using the design method in this section show that the pipe meets all of the strength-limit-state requirements.

Eq. 12.12.2.2-2 uses the constrained soil modulus, M_s , as the soil property. Note that the soil prism load is used as input, rather than the reduced load used to compute thrust.

This check should be completed to determine that the expected field deflection based on thrust and flexure is lower than the maximum allowable deflection for the project.

Thrust and hoop strain in the pipe wall are defined positive for compression.

There are no standard values for the deflection lag factor. Values from 1.0 to 6.0 have been recommended. The highest values are for installations with quality backfill and low initial deflections and do not generally control designs. A value of 1.5 provides some allowance for increase in deflection over time for installations with initial deflection levels of several percent.

The bedding coefficient, K_B , varies from 0.083 for full support to 0.110 for line support at the invert. Haunching is always specified to provide good support; however, it is still common to use a value of K_B equal to 0.10 to account for inconsistent haunch support.

Figure C12.12.2.2-1—Schematic for Thermoplastic Pipe Terms

12.12.3—Safety Against Structural Failure

12.12.3.1—General

Buried thermoplastic culverts shall be investigated at the strength limit states for thrust, general and local buckling, and combined strain.

12.12.3.2—Section Properties

Section properties for thermoplastic pipe, including wall area, moment of inertia, and profile geometry

C12.12.3.1

Total compressive strain in a thermoplastic pipe can cause yielding or buckling, and total tensile strain can cause cracking.

C12.12.3.2

Historically, AASHTO bridge specifications have contained minimum values for the moment of inertia

should be determined from cut sections of pipe or obtained from the pipe manufacturer.

and wall area of thermoplastic pipe; however, these values have been minimum values and are not meaningful for design. This is particularly so since provisions to evaluate local buckling were introduced in 2001. These provisions require detailed profile geometry that varies with manufacturer. Thus, there is no way to provide meaningful generic information on section properties. A convenient method for determining section properties for profile wall pipe is to make optical scans of pipe wall cross-sections and determine the properties with a computer drafting program.

12.12.3.3—Chemical and Mechanical Requirements

Mechanical properties for design shall be as specified in Table 12.12.3.3-1.

Except for buckling, the choice of either initial or long-term mechanical property requirements, as appropriate for a specific application, shall be determined by the Engineer. Investigation of general buckling shall be based on the value of modulus of elasticity that represents the design life of the project.

C12.12.3.3

Properties in Table 12.12.3.3-1 include “initial” and long-term values. No product standard requires determining the actual long-term properties; thus, there is some uncertainty in the actual values. However, pipe designed with the Table 12.12.3.3-1 values for 50-year modulus of elasticity have performed well, and the properties are assumed to be reasonably conservative. Values for a modulus of elasticity for a 75-year design life have been estimated from relaxation tests on PVC, PP, and PE in parallel plate tests. The tests were conducted for over two years and show that the modulus of elasticity reduces approximately linearly with the logarithm of time. Further, with a log-linear extrapolation, the differences between 50-year and 75-year modulus values are very small. These values should be reasonably conservative, with the same reliability as the 50-year values. Pipe and thermoplastic resin suppliers should be asked to provide confirmation of long-term modulus values for any particular product. The 100-Year Mechanical Properties in Table 12.12.3.3-1 for HDPE (per AASHTO M 294) and PP (per AASHTO M 330) are based off research performed by Hsuan (2012), McGrath et al. (2009), and Bass et al. (2012) for use in design in jurisdictions that have material specifications that allow for 100-year service thermoplastic pipe installations. Jurisdictions that allow 100-year service life installations for thermoplastic pipe may have additional testing requirements beyond what are included in AASHTO M 294 and M 330. Values should meet or exceed those provided in Table 12.12.3.3-1. Where service life is in excess of the Table 12.12.3.3-1 values, test data may be used for the desired life.

The service long-term tension strain limit and the factored compression strain limit in Table 12.12.3.3-1 need to be multiplied by the appropriate resistance factors to obtain the strain limits.

Table 12.12.3.3-1—Mechanical Properties of Thermoplastic Pipe

Type of Pipe	Minimum Cell Class	Service Long-Term Tension Strain Limit, ϵ_{st} (%)	Factored Compression Strain Limit, ϵ_{vc} (%)	Initial		50-year		75-year		100-year

12.12.3.4—Thrust

Loads on buried thermoplastic pipe shall be based on the soil prism load, modified as necessary to consider the effects of pipe–soil interaction. Calculations shall consider the duration of a load when selecting pipe properties to be used in design. Live loads need not be considered for the long-term loading condition.

12.12.3.5—Factored and Service Loads

The factored thrust shall be taken as:

$$T_u = \left[\eta_{EV} \left(\gamma_{EV} K_2 VAF P_{sp} + \gamma_{WA} P_w \right) + \eta_{LL} \gamma_{LL} P_L C_L F_1 F_2 \right] \frac{D_o}{2} \quad (12.12.3.5-1)$$

The service thrust shall be taken as:

C12.12.3.4

Because of the time-dependent nature of thermoplastic pipe properties, the load will vary with time.

Time of loading is an important consideration for some types of thermoplastic pipe. Live loads and occasional flood conditions are normally considered short-term loads. Earth loads or permanent high groundwater are normally considered long-term loads.

C12.12.3.5

For η factors, refer to Article 12.5.4 regarding assumptions about redundancy for earth loads and live loads.

The factor, K_2 , is introduced to consider variation in thrust around the circumference, which is necessary when combining thrust with moment or thrust due to earth and live load under shallow fill. K_2 is set at 1.0 to determine thrust at the springline and 0.6 to determine thrust at the crown. The term, P_L , is also modified for this reason in later Articles.

$$T_s = \left[K_2 VAF P_{sp} + P_L C_L F_1 F_2 + P_w \right] \frac{D_o}{2} \quad (12.12.3.5-2)$$

in which:

$$VAF = 0.76 - 0.71 \left(\frac{S_H - 1.17}{S_H + 2.92} \right) \quad (12.12.3.5-3)$$

$$S_H = \frac{\phi_s M_s R}{E_p A_g} \quad (12.12.3.5-4)$$

$$C_L = \frac{\ell_w}{D_o} \leq 1.0 \quad (12.12.3.5-5)$$

$$F_1 = \frac{0.75 D_o}{\ell_w} \geq F_{\min} \quad (12.12.3.5-6)$$

$$F_{\min} = \frac{15}{D_i} \geq 1 \quad (12.12.3.5-7)$$

$$F_2 = \frac{0.95}{1 + 0.6 S_H} \quad (12.12.3.5-8)$$

where:

- T_u = factored thrust per unit length (lb/in.)
- T_s = service thrust per unit length (lb/in.)
- P_L = live load pressure, as specified in Article 3.6.1.2.6
- ℓ_w = live load distribution width in the circumferential direction, as specified in Article 3.6.1.2.6
- $K_{\gamma E}$ = installation factor, typically taken as 1.5 to provide traditional safety. Use of a value less than 1.5 requires additional monitoring of the installation during construction and provisions for such monitoring shall be provided on the contract documents.

Figure C3.11.3-1 shows the effect of groundwater on the earth pressure. P_{sp} does not include the hydrostatic pressure. P_{sp} is the pressure due to the weight of soil above the pipe and should be calculated based on the wet density for soil above the water table and based on the buoyant density for soil below the water table. See Table 3.5.1-1 for common unit weights.

In computing ℓ_w , add axle spacing (and increase total live load) if the depth is sufficient for axle loads to interact.

The factor, $K_{\gamma E}$, is introduced to provide the same safety level as traditionally used for thermoplastic culverts. Designers may consider using values of $K_{\gamma E}$ as low as 1.0 provided that procedures are implemented to ensure compliance with construction specifications. For culvert designs completed with an installation factor less than 1.5, the designer is required to specify additional minimum performance measures such as testing, monitoring, construction controls, and backfill requirements including active monitoring of the backfill gradation and compaction (see Article 30.7.4 of the *AASHTO LRFD Bridge Construction Specifications*). The construction controls include deflection measurements and shall require the Contractor to submit and get approval from the Owner's Engineer for his/her construction plan to be used to achieve the more stringent performance measures which allowed for the use of a smaller installation factor in the design. Backfill placement and monitoring shall be done at levels along the side of the culvert and includes measurement of change in vertical pipe diameter when the backfill reaches the top of the pipe. As the backfill nears the top of pipe the vertical pipe diameter should be greater than the vertical diameter prior to backfilling, but not more than three percent greater than the vertical diameter

K_2 = coefficient to account for variation of thrust around the circumference
 = 1.0 for thrust at the springline
 = 0.6 for thrust at the crown

$$VAF = \text{vertical arching factor}$$
$$S_H = \text{hoop stiffness factor}$$

P_w = hydrostatic water pressure at the springline of the pipe (psi)

C_L = live load distribution coefficient

η_{EV} = load modifier as specified in Article 1.3.2, as it applies to vertical earth loads on culverts

γ_{EV} = load factor for vertical pressure from dead load of earth fill, as specified in Article 3.4.1

P_{sp} = soil prism pressure, EV, evaluated at pipe springline (psi)

γ_{WA} = load factor for hydrostatic pressure, as specified in Article 3.4.1

η_{LL} = load modifier as specified in Article 1.3.2, as it applies to live loads on culverts

γ_{LL} = load factor for live load, as specified in Article 3.4.1

P_L = live load pressure, LL , with dynamic load allowance (psi)

 ϕ_s = resistance factor for soil stiffness

prior to backfilling. When construction controls are implemented and the project specifications call for the total length of the pipe to be inspected and the vertical and horizontal deflection be measured no sooner than 30 days after backfill/embankment is completed, a value of $K_{TE}=1.0$ may be used for design.

The use of the *VAF* is based on the behavior, demonstrated by Burns and Richard (1964), that pipe with high hoop-stiffness ratios (S_H , ratio of soil stiffness to pipe hoop stiffness) carry substantially less load than the weight of the prism of soil directly over the pipe. This behavior was demonstrated experimentally by Hashash and Selig (1990) and analytically by Moore (1995). McGrath (1999) developed the simplified form of the equation presented in this Section.

The *VAF* approach is only developed for the embankment load case. No guidance is currently available to predict the reduced loads on pipe in trench conditions. The only trench load theory proposed for flexible pipe was that by Spangler, which does not have good guidance on selection of input parameters. It is conservative to use the *VAF* approach as presented for embankments.

If evaluating the short-term load condition, then use the initial modulus of elasticity to compute S_H . Similarly, if evaluating the long-term loading condition, then use the long-term modulus of elasticity to compute S_H .

The term, ϕ_s , appears in Eq. 12.12.3.5-4 to account for variability in backfill compaction. A lower level of compaction increases the applied thrust force on the pipe.

M_s = secant constrained soil modulus, as specified in Table 12.12.3.5-1 or Table 12.12.3.5-3 (ksi)

R = radius from center of pipe to centroid of pipe profile (in.)

E_p = short- or long-term modulus of pipe material as specified in Table 12.12.3.3-1 (ksi)

A_g = gross area of pipe wall per unit length of pipe (in.²/in.)

D_o = outside diameter of pipe (in.)

$LLDF$ = live load distribution factor through earth fills in Article 3.6.1.2.6

In the absence of site-specific data, the secant constrained soil modulus, M_s , may be selected from Table 12.12.3.5-1 based on the backfill type and density and the geostatic earth pressure, P_{sp} . Linear interpolation between soil stress levels may be used for the determination of M_s . If crushed stone backfill is used, the secant constrained modulus, M_s , may be selected from Table 12.12.3.5-3.

For culverts in embankment or wide trench installations under depths of fill up to 10.0 ft, the secant constrained soil modulus, M_s , selected from Table 12.12.3.5-1 or Table 12.12.3.5-3 shall be based on the backfill type and density conditions for a width of one-half diameter on each side of the culvert, but never less than 18.0 in. on each side of the culvert. For culverts under depths of fill greater than 10.0 ft, the secant constrained soil modulus, M_s , selected shall be based on the backfill type and density conditions for a width of one diameter on each side of the culvert.

For selecting values of the constrained soil modulus, M_s , editions of these Specifications prior to 2012 contained the commentary, "Suggested practice is to design for a standard Proctor backfill density five percent less than specified by the contract documents." This statement is not considered necessary with the addition of post-construction inspection guidelines to the *AASHTO LRFD Bridge Construction Specifications*, which should provide reasonable assurance that the design condition is achieved.

For culverts in trench installations under depths of fill greater than 10.0 ft, evaluation of the values of M_s for in-situ soil for a width one diameter either side of the pipe is not necessary, provided the in-situ soil has adequate vertical and lateral stiffness. Stable trench walls during the excavation process are predictive of adequate vertical and lateral stiffness.

Installation in narrow trenches reduces the vertical load, provided vertical stiffness of the soil is adequate to carry the load that is distributed around the pipe due to arching, as represented by the VAF in the design method and adequate space is preserved at the side of the pipe to place and compact backfill. The minimum trench widths provided in the *AASHTO LRFD Bridge Construction Specifications* are set to provide adequate space. Narrow trenches yield a desirable level of conservatism, since the transfer of the load to in-situ trench wall is not considered in flexible pipe design.

If the structural backfill material is crushed stone, then the secant constrained soil modulus, M_s , values shown in Table 12.12.3.5-3 may be used. If an aggregate other than granite, limestone, or quartz is used, or if the aggregate type is unknown, the constrained soil modulus values for crushed limestone may be conservatively applied. These constrained modulus values are independent of burial depth. While it is not common practice to monitor density of crushed stone backfills, experience has found that a modest compaction effort improves culvert performance and allows the use of the compacted values.

The width of structural backfill is an important consideration when the in situ soil in the trench wall or the embankment fill at the side of the structural backfill is soft. As of 2024, only the American Water Works Association's (AWWA's) *Manual of Water Supply Practices—M45* addresses this issue.

The constrained modulus is the slope of the secant from the origin of the curve to a point on the curve corresponding to the soil prism pressure, P_{sp} , Figure C12.12.3.5-1.

The constrained modulus may also be determined experimentally using the stress-strain curve resulting from a uniaxial strain test on a sample of soil compacted to the field-specified density.

Figure C12.12.3.5-1—Schematic One-Dimensional Stress-Strain Curve of Soil Backfill

Table 12.12.3.5-1— M_s Based on Soil Type and Compaction Condition

P_{sp} Stress Level (psi)	Sn-100 (ksi)	Sn-95 (ksi)	Sn-90 (ksi)	Sn-85 (ksi)
1.0	2.350	2.000	1.275	0.470
5.0	3.450	2.600	1.500	0.520
10.0	4.200	3.000	1.625	0.570
20.0	5.500	3.450	1.800	0.650
40.0	7.500	4.250	2.100	0.825
60.0	9.300	5.000	2.500	1.000
P_{sp} Stress Level (psi)		Si-95 (ksi)	Si-90 (ksi)	Si-85 (ksi)
1.0		1.415	0.670	0.360
5.0		1.670	0.740	0.390
10.0		1.770	0.750	0.400
20.0		1.880	0.790	0.430
40.0		2.090	0.900	0.510
60.0				
P_{sp} Stress Level (psi)		Cl-95 (ksi)	Cl-90 (ksi)	Cl-85 (ksi)
1.0		0.530	0.255	0.130
5.0		0.625	0.320	0.175

20.0		0.740	0.395	0.230
40.0		0.815	0.460	0.285
60.0		0.895	0.525	0.345

1. The soil types are defined by a two-letter designation that indicates general soil classification, Sn for sands and gravels, Si for silts, and Cl for clays. Specific soil groups that fall into these categories, based on ASTM D2487 and AASHTO M 145, are listed in Table 12.12.3.5-2.
2. The numerical suffix to the soil type indicates the compaction level of the soil as a percentage of maximum dry density determined in accordance with AASHTO T 99.

Table 12.12.3.5-2—Equivalent ASTM and AASHTO Soil Classifications

Basic Soil Type (1)	ASTM D2487	AASHTO M 145
Sn (Gravelly sand, SW)	SW, SP (2) GW, GP sands and gravels with 12% or less fines	A-1, A-3 (2)
Si (Sandy silt, ML)	GM, SM, ML also GC and SC with less than 20% passing a No. 200 sieve	A-2-4, A-2-5, A-4
Cl (Silty clay, CL)	CL, MH, GC, SC also GC and SC with more than 20% passing a No. 200 sieve	A-2-6, A-2-7, A-5, A-6

1. The soil classification listed in parentheses is the type that was tested to develop the constrained soil modulus values in Table 12.12.3.5-1. The correlations to other soil types are approximate.
2. Uniformly graded materials with an average particle size smaller than a No. 40 sieve shall not be used as backfill for thermoplastic culverts unless specifically allowed in the contract documents and special precautions are taken to control moisture content and monitor compaction levels.

Table 12.12.3.5-3—Constrained Modulus, M_s , Values for Crushed Stone Backfill Materials

Aggregate	Maximum Particle Size (in.)	Constrained Modulus, M_s (ksi)	
		Dumped	Compacted
Granite	0.75	7.000	8.500
	1.50	3.500	5.000
Limestone	0.75	3.500	5.500
Quartz	0.75	5.500	7.500

12.12.3.6—Handling and Installation Requirements

The flexibility factor, FF , in./kip shall be taken as:

$$FF = \frac{S^2}{EI} \quad (12.12.3.6-1)$$

where:

- I = moment of inertia (in.⁴/in.)
 E = initial modulus of elasticity (ksi)
 S = diameter of pipe (in.)

The flexibility factor, FF , shall be limited as specified in Article 12.5.6.3.

12.12.3.7—Soil Prism

The soil prism load shall be calculated as a pressure representing the weight of soil above the pipe springline. The pressure shall be calculated for three conditions:

C12.12.3.7

The soil prism load and VAF serve as a common reference for the load on all types of pipe.

The soil prism calculation needs to consider the unit weight of the backfill over the pipe. Use the wet unit weight above the water table and the buoyant unit weight below the water table. In cases where the water table fluctuates, multiple conditions may need to be evaluated.

Figure C3.11.3-1 shows the effect of groundwater on the earth pressure. See Table 3.5.1-1 for common unit weights.

- If the water table is above the top of the pipe and at or above the ground surface:

$$P_{sp} = \frac{\left(H + 0.11 \frac{D_o}{12}\right) \gamma_b}{144} \quad (12.12.3.7-1)$$

- If the water table is above the top of the pipe and below the ground surface:

$$P_{sp} = \frac{1}{144} \left[\left[\left(H_w - \frac{D_o}{24} \right) + 0.11 \frac{D_o}{12} \right] \gamma_b + \left[H - \left(H_w - \frac{D_o}{24} \right) \right] \gamma_s \right] \quad (12.12.3.7-2)$$

- If the water table is below the top of the pipe:

$$P_{sp} = \frac{\left(H + 0.11 \frac{D_o}{12}\right) \gamma_s}{144} \quad (12.12.3.7-3)$$

where:

P_{sp} = soil prism pressure (EV), evaluated at pipe springline (psi)

$$D_o = \text{outside diameter of pipe (in.)}$$
$$\gamma_b = \text{unit weight of buoyant soil (lb/ft}^3\text{)}$$

H = height of fill over top of pipe (ft)

$$H_w = \text{height of water table above springline of pipe (ft)}$$
$$\gamma_s = \text{wet unit weight of soil (lb/ft}^3\text{)}$$

12.12.3.8—Hydrostatic Pressure

The pressure due to ground water shall be calculated as:

$$P_w = \frac{\gamma_w K_{wa} H_w}{144} \quad (12.12.3.8-1)$$

where:

P_w = hydrostatic water pressure at the springline of the pipe (psi)

$$\gamma_w = \text{unit weight of water (lb/ft}^3\text{)}$$

K_a = factor for uncertainty in level of groundwater table

C12.12.3.8

Hydrostatic loading due to external water pressure should be calculated in all cases where water table may be above the pipe springline at any time. This load contributes to hoop thrust but does not affect deflection.

There is often uncertainty in the level of the groundwater table and its annual variations. The designer

may use the factor K_{wv} with values up to 1.3 to account for this uncertainty or may select conservative values of H_w with a lower value of K_{wv} but not less than 1.

12.12.3.9—Live Load

The provisions of Article 12.6.1 shall apply.

12.12.3.10—Wall Resistance

12.12.3.10.1—Resistance to Axial Thrust

12.12.3.10.1a—General

Elements of profile wall pipe shall be designed to resist local buckling. To determine local buckling resistance, profile-wall pipe geometry shall be idealized as specified herein and an effective area determined in accordance with the following provisions.

12.12.3.10.1b—Local Buckling Effective Area

For the determination of buckling resistance, profile wall pipe shall be idealized as straight elements. Each element shall be assigned a width based on the clear distance between the adjoining elements and a thickness based on the thickness at the center of the element. The idealization of a typical corrugated profile should be based on the approximation in Figure 12.12.3.10.1b-1.

Figure 12.12.3.10.1b-1—Typical and Idealized Cross-section of Profile Wall Pipe

To evaluate the resistance to axial thrust, the area of the profile shall be reduced to an effective area, A_{eff} , for local buckling effects. The effective area of the profile shall be determined by subtracting the ineffective area of each element from the gross section area, as:

$$A_{eff} = A_g - \frac{\sum (w - b_e)t}{\omega} \quad (12.12.3.10.1b-1)$$

in which:

$$b_e = \rho w \quad (12.12.3.10.1b-2)$$

$$\rho = \frac{\left(1 - \frac{0.22}{\lambda}\right)}{\lambda} \quad (12.12.3.10.1b-3)$$

C12.12.3.10.1b

To complete the local buckling calculations, the profile is idealized into a group of rectangular elements. To complete the idealization, it should include:

- The actual total area.
- If the crest element is curved, it should be idealized at the centroid of the curvature. The idealized element need not touch the idealized webs.

See McGrath et al. (2009) for guidance on other profile types.

The resistance to local buckling is based on the effective width concept used by the cold formed steel industry. This theory assumes that even though buckling is initiated in the center of a plate element, the element still has substantial post-buckling strength at the edges where the element is supported. This concept is demonstrated in Figure C12.12.3.10.1b-1.

Figure C12.12.3.10.1b-1—Effective Width Concept

$$\lambda = \left(\frac{w}{t} \right) \sqrt{\frac{\epsilon_{yc}}{k}} \geq 0.673 \quad (12.12.3.10.1b-4)$$

where:

- A_{eff} = effective area of pipe wall per unit length of pipe (in.²/in.)
- b_e = element effective width (in.)
- ρ = effective width factor
- λ = slenderness factor
- ω = spacing of corrugation (in.), as specified in Figure 12.12.3.10.1b-1
- ϵ_{yc} = factored compressive strain limit, as specified in Table 12.12.3.3-1
- A_g = gross area of pipe wall per unit length of pipe (in.²/in.)
- t = thickness of element (in.)
- w = total clear width of element between supporting elements (in.)
- k = plate buckling coefficient, $k = 4$ for supported elements, $k = 0.43$ for unsupported elements, such as free standing ribs

As an alternate to determining the effective area by the calculation procedure presented above, the results of the stub compression test, AASHTO T 341, may be used, in which case the effective area, A_{eff} , shall satisfy:

$$A_{eff} = \frac{P_{st} K_t}{F_u} \leq A_g \quad (12.12.3.10.1b-5)$$

in which:

- P_{st} = stub compression capacity from AASHTO T 341 (kip/in.)
- K_t = time factor, as specified in Table 12.12.3.10.1b-1
- F_u = material yield strength for design load duration (ksi)

Table 12.12.3.10.1b-1—Time Factor

Time Period	PE	PP	PVC
Initial	0.9	0.9	0.95
50 yr	0.3	0.3	0.6
75 yr (est.)	0.25	0.25	0.5

The local buckling evaluation reduces the capacity of pipe wall sections with high ratios of width to thickness.

The calculations in Eqs. 12.12.3.10.1b-1 to 12.12.3.10.1b-4 must be repeated for each element in the idealized profile.

The plate buckling coefficient is analogous to the effective length factor, k , in column buckling.

The stub compression test has been incorporated as a requirement into AASHTO product standards M 294, M 330, and M 304. The test data should be readily available from manufacturers and quality control tests.

Values for the time factor, K_t , are not included for determining effective area by stub compression for designs requiring 100-year mechanical properties. Where service life in excess of 75 years is required, the effective area, A_{eff} , shall be determined by calculation using Eq. 12.12.3.10.1b-1.

12.12.3.10.1c—Compression Strain

The factored compressive strain due to factored thrust, ϵ_{uc} , and the service compressive strain due to service thrust, ϵ_{sc} , shall be taken as:

$$\epsilon_{uc} = \frac{T_u}{1,000(A_{eff} E_p)} \quad (12.12.3.10.1c-1)$$

$$\epsilon_{sc} = \frac{T_s}{1,000(A_{eff} E_p)} \quad (12.12.3.10.1c-2)$$

where:

- ϵ_{uc} = factored compressive strain due to thrust
- ϵ_{sc} = service compressive strain due to thrust
- T_u = factored thrust per unit length (lb/in.)
- T_s = service thrust per unit length (lb/in.)
- A_{eff} = effective area of pipe wall per unit length of pipe (in.²/in.)
- E_p = short-term modulus for short-term loading or long-term modulus of pipe material for long-term loading as specified in Table 12.12.3.3-1 (ksi)

12.12.3.10.1d—Thrust Strain Limits

The factored compression strain due to thrust, ϵ_{uc} , shall satisfy:

$$\epsilon_{uc} \leq \phi_T \epsilon_{yc} \quad (12.12.3.10.1d-1)$$

where:

- ϵ_{uc} = factored compressive strain due to thrust
- ϕ_T = resistance factor for thrust effects
- ϵ_{yc} = factored compression strain limit of the pipe wall material, as specified in Table 12.12.3.3-1

12.12.3.10.1e—General Buckling Strain Limits

The factored compression strain due to thrust, incorporating local buckling effects, ϵ_{uc} , shall satisfy:

$$\epsilon_{uc} \leq \phi_{bck} \epsilon_{bck} \quad (12.12.3.10.1e-1)$$

The nominal strain capacity for general buckling of the pipe shall be determined as:

$$\epsilon_{bck} = \frac{1.2 C_n (E_p I_p)^{\frac{1}{3}}}{A_{eff} E_p} \left[\frac{\phi_s M_s (1-2\nu)}{(1-\nu)^2} \right]^{\frac{2}{3}} R_h \quad (12.12.3.10.1e-2)$$

in which:

C12.12.3.10.1e

The equations for global resistance presented here are a conservative simplification of the continuum buckling theory presented by Moore (1990). Detailed analysis using the full theory may be applied in lieu of the calculations in this Section.

$$R_h = \frac{11.4}{11 + \frac{D}{12H}} \quad (12.12.3.10.1e-3)$$

where:

ϵ_{uc} = factored compressive strain due to thrust
 ϕ_{bck} = resistance factor for global buckling
 ϵ_{bck} = nominal strain capacity for general buckling

R_h = correction factor for backfill soil geometry

The term, ϕ_s , appears in this expression for ϵ_{bck} to account for backfills compacted to levels below that specified in the design. Lower levels of compaction increases the thrust force in the pipe.

For designs meeting all other requirements of these specifications and the *AASHTO LRFD Bridge Construction Specifications*, the correction for backfill soil geometry, R_h , is equal to value at left.

The complete theory proposed by Moore (1990) provides variations in R_h that consider nonuniform backfill support. In the extreme case where the width of structural backfill at the side of the culvert is 0.1 times the span and the modulus of the soil outside of the structural backfill is 0.1 times the modulus of the backfill, then:

$$R_h = \frac{20}{56 + \frac{D}{12H}} \quad (C12.12.3.10.1e-1)$$

C_n = calibration factor to account for nonlinear effects
 = 0.55

E_p = short- or long-term modulus of pipe material, as specified in Table 12.12.3.3-1 (ksi)

I_p = moment of inertia of pipe profile per unit length of pipe (in.⁴/in.)

A_{eff} = effective area of pipe profile per unit length of pipe (in.²/in.)

ϕ_s = resistance factor for soil pressure

M_s = secant constrained soil modulus, as specified in Table 12.12.3.5-1 (ksi)

ν = Poisson's ratio of soil

D = diameter to centroid of pipe profile (in.)

H = height of fill over top of pipe (ft)

Poisson's ratio is used to convert the constrained modulus of elasticity to the plane strain modulus. Values for Poisson's ratio of soils are provided in many geotechnical references. One reference is Selig (1990).

12.12.3.10.2—Bending and Thrust Strain Limits

12.12.3.10.2a—General

To ensure adequate flexural capacity the combined strain at the extreme fibers of the pipe profile must be evaluated at the allowable deflection limits against the limiting strain values.

12.12.3.10.2b—Combined Strain

If summation of axial strain, ϵ_{uc} , and bending strain, ϵ_b , produces tensile strain in the pipe wall, the combined

C12.12.3.10.2b

The criteria for combined compressive strain are based on limiting local buckling. A higher strain limit is

strain at the extreme fiber where flexure causes tension shall satisfy:

$$\varepsilon_f - \varepsilon_{uc} < \phi_f \varepsilon_{yt} \quad (12.12.3.10.2b-1)$$

The combined strain at the extreme fiber where flexure causes compression shall satisfy:

$$\varepsilon_f + \varepsilon_{uc} < \phi_T (1.5 \varepsilon_{yc}) \quad (12.12.3.10.2b-2)$$

where:

- ε_f = factored strain due to flexure
- ε_{uc} = factored compressive strain due to thrust
- ε_{yt} = service long-term tension strain limit of the pipe wall material, as specified in Table 12.12.3.3-1
- ϕ_f = resistance factor for flexure
- ϕ_T = resistance factor for thrust
- ε_{yc} = factored compression strain limit of the pipe wall material, as specified in Table 12.12.3.3-1

In the absence of a more detailed analysis, the flexural strain may be determined based on the empirical relationship between strain and deflection as:

$$\varepsilon_f = \gamma_{EV} D_f \left(\frac{c}{R} \right) \left(\frac{\Delta_f}{D} \right) \quad (12.12.3.10.2b-3)$$

in which:

$$\Delta_f = \Delta_A - \varepsilon_{sc} D \quad (12.12.3.10.2b-4)$$

where:

- ε_f = factored strain due to flexure
- ε_{sc} = service compressive strain due to thrust
- Δ_f = reduction of vertical diameter due to flexure (in.)
- γ_{EV} = load factor for vertical pressure from dead load of earth fill, as specified in Article 3.4.1
- D_f = shape factor, as specified in Table 12.12.3.10.2b-1. The shape factors for corrugated PE and PP pipes can be reduced by 1.0 from the table values to account for the effect of the low hoop stiffness ratio.
- c = the larger of the distance from neutral axis of profile to the extreme innermost or outermost fiber (in.)
- R = radius from center of pipe to centroid of pipe profile (in.)
- D = diameter to centroid of pipe profile (in.)
- Δ_A = total allowable deflection of pipe, reduction of vertical internal diameter (in.)

allowed for combined strains because under bending, the web elements have a low stress near the centroid of the element and are thus unlikely to buckle. Thus the unbuckled web elements increase the stability of the crest and valley elements.

The strain limit for combined compression strain is 50 percent higher than that for hoop compression alone because the web elements, which experience low strains due to bending, are not likely to buckle, thus increasing the stability of elements near the crest and valley. While this behavior would be more accurately modeled as an increase in the k factor of Eq. 12.12.3.10.1b-4, the increase in the limiting strain is considered adequate for this simplified design method.

For thrust capacity, the section is limited by consideration of hoop compression capacity alone. The check of combined compression strain, hoop plus bending, is used to limit the allowable pipe deflection.

Elements subjected primarily to bending (such as a web element in Figure 12.12.3.10.1b-1 when the pipe is deflected) are not highly stressed near the centroid, where buckling initiates, and theoretical k factors for plates in bending are greater than 20. To simplify the analysis for combined bending and thrust, elements, such as the web whose centroid is within $c/3$ of the centroid of the entire profile wall, may be analyzed only for the effect of hoop compression strains. That is, increases in strain due to bending may be ignored.

Past practice has used tensile strain limits specified in Table 12.12.3.3-1, with no guidance on ultimate strain limits. For purposes of design calculations, assume that ultimate tensile strain capacity is 50 percent greater than the service capacities provided in Table 12.12.3.3-1.

A higher strain limit is allowed under combined bending and compression. This increase is permitted because the web element under flexure has a low stress at the center of the element, reducing the likelihood of buckling, and allowing it to provide more stability to the crest and valley elements.

Flexural strains are always taken as positive. The service compressive strain is used for determination of the factored strain due to flexure instead of the factored compressive strain. The use of the factored compressive strain would result in an unconservative flexural strain demand.

The empirical shape factor is used in the design of fiberglass pipe and is presented in AWWA's *Manual of Water Supply Practices—M45*. It demonstrates that bending strains are highest in low stiffness pipe backfilled in soils that require substantial compactive effort (silts and clays), and is lowest in high stiffness pipe backfilled in soils that require little compactive effort (sands and gravels).

Table 12.12.3.10.2b-1 does not cover all possible backfills and density levels. Designers should interpolate

or extrapolate the Table as necessary for specific projects.

More detailed analyses must consider the likelihood of inconsistent soil support to the pipe in the haunch zone, and of local deformations during placement and compaction of backfill.

Bending strains typically cannot be accurately predicted during design due to variations in backfill materials and compactive effort used during installation. Installation deflection limits are specified in the construction specifications to assure that design parameters are not exceeded.

The deflection design limit is five percent reduction of the vertical diameter, as specified in the construction specification. The pipe must be designed to permit this deflection, unless extraordinary measures are specified in contract documents to minimize compactive effort and to control deflections.

The *AASHTO LRFD Bridge Construction Specifications* currently restrict the allowable total vertical deflection to five percent.

Table 12.12.3.10.2b-1—Shape Factors, D_f , based on Pipe Stiffness, Backfill, and Compaction Level

Pipe Stiffness (F/Δ_p , ksi) $= EI / 0.149 R^3$	Pipe Zone Embedment Material and Compaction Level			
	Gravel (1)		Sand (2)	
	Dumped to Slight (3)	Moderate to High (4)	Dumped to Slight (3)	Moderate to High (4)
0.009	5.5	7.0	6.0	8.0
0.018	4.5	5.5	5.0	6.5
0.036	3.8	4.5	4.0	5.5
0.072	3.3	3.8	3.5	4.5

1. GW, GP, GW-GC, GW-GM, GP-GC, and GP-GM per ASTM D2487 (includes crushed rock)
2. SW, SP, SM, SC, GM, and GC or mixtures per ASTM D2487
3. <85% of maximum dry density per AASHTO T 99, < 40% relative density (ASTM D4253 and D4254)
4. ≥85% of maximum dry density per AASHTO T 99, ≥ 40% relative density (ASTM D4253 and D4254)

12.12.4—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 30 of the *AASHTO LRFD Bridge Construction Specifications*.

12.13—STEEL TUNNEL LINER PLATE

12.13.1—General

The provisions of this Article shall apply to the structural design of steel tunnel liner plates. Construction shall conform to Section 25 of the *AASHTO LRFD Bridge Construction Specifications*.

The tunnel liner plate may be two-flange, fully corrugated with lapped longitudinal seams or four-flange, partially corrugated with flanged longitudinal seams. Both types shall be bolted together to form annular rings.

C12.13.1

The supporting capacity of a nonrigid tunnel lining, such as a steel liner plate, results from its ability to deflect under load, so that side restraint developed by the lateral resistance of the soil constrains further deflection. Thus, deflection tends to equalize radial pressures and to load the tunnel liner as a compression ring.

12.13.2—Loading

The provisions for earth loads given in Article 3.11.5 shall not apply to tunnels.

12.13.2.1—Earth Loads

The provisions of Article 12.4.1 shall apply. When more refined methods of soil analysis are not employed, the earth pressure may be taken as:

$$W_E = C_{dt} \gamma_s S \quad (12.13.2.1-1)$$

where:

- C_{dt} = load coefficient for tunnel installation, specified in Figure 12.13.2.1-1
- γ_s = total unit weight of soil (ksf)
- W_E = earth pressure at the crown (ksf)
- S = tunnel diameter or span (ft)

C12.13.2

The earth load to be carried by the tunnel liner is a function of the type of soil. In granular soil with little or no cohesion, the load is a function of the angle of internal friction of the soil and the diameter of the tunnel. In cohesive soils such as clays, the load to be carried by the tunnel liner is dependent on the shearing strength of the soil above the roof of the tunnel.

C12.13.2.1

Eq. 12.13.2.1-1 is a form of the Marston formula. It proportions the amount of total overburden pressure acting on the tunnel based on the internal friction angle of the soil to be tunneled.

In the absence of adequate borings and soil tests, use $\phi_f = 0$ when calculating W_E .

Figure 12.13.2.1-1—Diagram for Coefficient, C_{dt} , for Tunnel in Soil

in which:

H = height of soil over top of tunnel (ft)

0.375	0.625	—	—	0.625	A307	119

All nuts shall conform to ASTM A307, Grade A or better.

Circumferential seam bolts shall conform to ASTM A307 or better for all plate thicknesses.

Table 12.13.3.1-3—Mechanical Properties—Steel Tunnel Liner Plate (Plate before Cold Forming)

Minimum Tensile Strength	42.0 ksi
Minimum Yield Strength	28.0 ksi
Elongation, 2.0 in.	30%
Modulus of Elasticity	29,000 ksi

12.14—PRECAST REINFORCED CONCRETE THREE-SIDED STRUCTURES

12.14.1—General

The provisions herein shall apply to the design of precast reinforced concrete three-sided structures supported on a concrete footing foundation.

C12.14.1

Units may be manufactured using conventional structural concrete and forms (formed) or machine made using dry concrete and vibrating forms.

12.14.2—Materials

12.14.2.1—Concrete

Concrete shall conform to Article 5.4.2, except that evaluation of f'_c may also be based on cores.

12.14.2.2—Reinforcement

Reinforcement shall meet the requirements of Article 5.4.3, except that for welded wire fabric a yield strength of 65,000 psi may be used. For wire fabric, the spacing of longitudinal wires shall be a maximum of 8.0 in. Circumferential welded wire fabric spacing shall not be greater than 4.0 in. or less than 2.0 in. Prestressing, if used, shall be in accordance with Article 5.9.

12.14.3—Concrete Cover for Reinforcement

The minimum concrete cover for reinforcement in precast three-sided structures reinforced with welded wire fabric shall be taken as three times the wire diameter, but not less than 1.0 in., except for the reinforcement in the top of the top slab of structures covered by less than 2.0 ft of fill, in which case the minimum cover shall be taken as 2.0 in.

12.14.4—Geometric Properties

Except as noted herein, the shape of the precast three-sided structures may vary in span, rise, wall thickness, haunch dimensions, and curvature. Specific geometric properties shall be specified by the manufacturer. Wall thicknesses shall be a minimum of 8.0 in. for spans under 24.0 ft and 10.0 in. for 24.0 ft and larger spans.

12.14.5—Design

12.14.5.1—General

Designs shall conform to applicable sections of these Specifications, except as provided otherwise herein. Analysis shall be based on a pinned connection at the footing and shall take into account anticipated footing movement.

12.14.5.2—Distribution of Concentrated Load Effects in Top Slab and Sides

Distribution of wheel loads and concentrated loads for the top slab and sides of three-sided structures shall be taken as specified in Article 12.11.2.1.

12.14.5.3—Distribution of Concentrated Loads in Skewed Culverts

Wheel loads on skewed culverts shall be distributed using the same provisions as given for culverts with main reinforcement parallel to traffic. For culvert elements with skews greater than 15 degrees, the effect of the skew shall be considered in analysis.

12.14.5.4—Shear Transfer in Transverse Joints between Culvert Sections

The provisions of Article 4.6.2.10.4 shall apply.

In addition, except as provided herein, a means of shear transfer between adjacent units shall be provided in the top slab of structures having flat tops under less than 2.0 ft of fill and subjected to vehicular live loads. Shear transfer between adjacent units may be considered adequate where the thickness of the top slab is equal to or greater than:

- For prestressed slabs:

$$\frac{S}{28} \quad (12.14.5.4-1)$$

- For non-prestressed slabs:

$$\frac{(S + 10)}{30} \quad (12.14.5.4-2)$$

where:

S = clear span measured parallel to the joint with the adjacent section (ft)

C12.14.5.4

Flat-top structures with less than 2.0 ft of fill and with top slabs that are thinner than specified in this Article may experience differential deflection of adjacent units which can cause pavement cracking if a means of shear transfer is not utilized.

The specified minimum slab thickness and span-to-slab thickness ratios reflect years of experience in the design and construction of flat top three-sided structures and are influenced by Table 9.5(a) of ACI 318-08 and Table 8.9.2 of the *AASHTO Standard Specifications for Highway Bridges*, 17th ed. Past performance of flat top three-sided structures designed in accordance with these provisions provides additional support for this exception.

For skewed sections, design is based on the span measured parallel to the joint with the adjacent section. This is a longer span than measured perpendicular to the end walls. However, designing for a longer span provides additional reinforcement to address the non-uniform stresses introduced by the skewed geometry which are not explicitly considered for modest skew angles.

Arch-top structures, because of their geometry and interaction with the surrounding soil, do not exhibit significant differential deflections that could cause pavement cracking for structures with less than 2.0 ft of fill. Thus, the requirements of this Article do not apply to arch-top structures.

The minimum thickness provision of this Section pertains only to addressing the need for shear transfer between adjacent three-sided sections. All other provisions of this Specification must be met.

12.14.5.5—Span Length

When monolithic haunches inclined at 45 degrees are taken into account, negative reinforcement in walls and slabs may be proportioned on the basis of flexural moment at the intersection of the haunch and uniform depth member.

12.14.5.6—Resistance Factors

The provisions of Articles 12.5.5 and 1.3.1 shall apply as appropriate.

12.14.5.7—Crack Control

The provisions of Article 5.6.7 for buried structures shall apply.

12.14.5.8—Minimum Reinforcement

The provisions of Article 5.9.5.5 shall not be taken to apply to precast three-sided structures.

The primary flexural reinforcement in the direction of the span shall provide a ratio of reinforcement area to gross concrete area at least equal to 0.002. Such minimum reinforcement shall be provided at all cross-sections subject to flexural tension, at the inside face of walls, and in each direction at the top of slabs of three-sided sections with less than 2.0 ft of fill.

12.14.5.9—Deflection Control at the Service Limit State

The deflection limits for concrete structures specified in Article 2.5.2.6.2 shall be taken as mandatory and pedestrian usage as limited to urban areas.

12.14.5.10—Footing Design

Design shall include consideration of differential horizontal and vertical movements and footing rotations. Footing design shall conform to the applicable Articles in Sections 5 and 10.

12.14.5.11—Structural Backfill

Specification of backfill requirements shall be consistent with the design assumptions used. The contract documents should require that a minimum backfill compaction of 90 percent Standard Proctor Density be achieved to prevent roadway settlement adjacent to the structure. A higher backfill compaction density may be required on structures utilizing a soil-structure interaction system.

12.14.5.12—Scour Protection and Waterway Considerations

The provisions of Article 2.6 shall apply as appropriate.

12.15—FIBERGLASS PIPE**12.15.1—General**

The provisions of this Article shall apply to the structural design of solid wall buried fiberglass pipe.

C12.15.1

The provisions of this Article are based on Chapter 5 of AWWA's *Manual of Water Supply Practices—*

M45. The internal pressure design requirements of M45 have been omitted here, as culverts are typically designed for gravity flow.

Specific design requirements rely on the provisions for thermoplastic pipe as modified in this Article. Not all thermoplastic pipe design requirements are applicable to fiberglass pipe design.

12.15.2—Section Properties

Section properties for service and strength limit state calculations for solid wall fiberglass pipe shall be determined from the manufacturer's published nominal wall thickness, and from the nominal diameter requirements of ASTM D3262, Tables 2 and 3. Fiber-reinforced wall thickness shall be determined in accordance with ASTM D3567.

12.15.3—Mechanical Requirements

Solid wall fiberglass pipe mechanical properties shall be determined as specified in this Article.

12.15.3.1—Circumferential Flexural Modulus

The design value for circumferential flexural modulus of the pipe, E_{cf} , shall be calculated from pipe stiffness test results, conducted in accordance with ASTM D3262, using the pipe's fiber-reinforced wall thickness determined in accordance with Article 12.15.2.

12.15.3.2—Long-Term Ring-Bending Strain

The design value for long-term ring-bending strain, S_b , shall be determined from tests in accordance with ASTM D5365 using a water test solution with a pH between 5 and 9. Test data shall be statistically extrapolated to 75 years. Alternatively, the results from tests in accordance with ASTM D3681 may be used when tested in a solution of 1 N H₂SO₄, with the results extrapolated to 75 years.

12.15.4—Total Allowable Deflection

The total allowable deflection, Δ_A (in.), shall be 5.0 percent of the inside diameter of the pipe or a lower deflection as specified by the Engineer. The total allowable deflection and the upper deflection limit where remediation or replacement is required shall be prominently displayed in the construction documents.

C12.15.3

Because of the composite nature of fiberglass pipe, variety of manufacturing processes, and variables such as the amount, type, and orientation of fiber reinforcement, mechanical properties used in design must be actual properties from test results and measurements of the pipe in accordance with ASTM D3262 and ASTM D3567, as required in this Article.

C12.15.3.1

Appendix 2 of ASTM D2412 includes discussion on determining the circumferential flexural modulus from pipe stiffness test results.

C12.15.3.2

As fiberglass pipe was originally designed for sanitary sewer applications, testing in acid is common and results are generally available from manufacturers. Testing in acid gives conservative results over water, and, if the results are already available, eliminates the need for the manufacturer to perform additional testing in water.

C12.15.4

Higher stiffness fiberglass pipe is easily produced for specific installations by increasing the quantity of glass fiber reinforcement or the wall thickness, or both. The allowable deflection for higher stiffness pipes may need to be reduced.

12.15.5—Service Limit States

12.15.5.1—General

Similar to other types of buried flexible pipe, fiberglass pipe shall be installed in a manner that will ensure that external loads will not cause a long-term decrease in the vertical diameter of the pipe exceeding the total allowable deflection in Article 12.15.4.

12.15.5.2—Deflection Requirement

The deflection requirements for thermoplastic pipe in Article 12.12.2 shall apply with the total allowable deflection, Δ_A , as defined in Article 12.15.4, and total deflection, Δ_t , determined as:

$$\Delta_l = \frac{D_o K_B (D_L P_{sp} + C_L P_L)}{1,000 (E_{\sigma} I_p / R^3 + 0.061 M_s)} \quad (12.15.5.2-1)$$

where:

- | | | |
|------------|---|--|
| Δ_t | = | total deflection of pipe, expressed as a reduction of the vertical diameter and taken as positive for a reduction in the vertical diameter (in.) |
| D_o | = | outside diameter of pipe, as specified in Article 12.15.2 (in.) |
| K_B | = | bedding coefficient, as specified in Article 12.12.2.2 |
| D_L | = | deflection lag factor, as specified in Article 12.12.2.2 |
| P_{sp} | = | soil prism pressure, EV , evaluated at the top of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi) |
| C_L | = | live load distribution coefficient, as specified in Article 12.12.3.5 |
| P_L | = | service live load on pipe, as specified in Article 12.6.1 (psi) |
| E_{cf} | = | circumferential flexural modulus as defined in Article 12.15.3.1 (ksi) |
| I_p | = | moment of inertia of the fiber-reinforced pipe wall per unit length (in. ⁴ /in.) |
| R | = | radius of pipe to centroid of pipe wall (in.) |
| M_s | = | constrained soil modulus as specified in Table 12.12.3.5-1 (ksi) |

12.15.6—Safety Against Structural Failure

12.15.6.1—General

Buried fiberglass culverts shall be investigated at the strength limit states for flexure (ring-bending), global buckling, and flexibility limit.

C12.15.5.2

This Article is similar to Article 12.12.2.2 for thermoplastic pipe; however, the critical loading for fiberglass pipe occurs due to flexural tension at the invert. Axial compressive thrust in fiberglass pipe is not significant due to the solid wall and high modulus and is therefore ignored. However, the solid wall and high modulus do increase the service load on the pipe to the total soil prism load. Thus, Article 12.12.2.2 is adapted to fiberglass pipe by eliminating the thrust component of deflection and calculating the load as the soil prism pressure at the crown of the pipe.

12.15.6.2—Flexure

Factored long-term strain due to flexure shall satisfy:

$$\varepsilon_f \leq \phi_f S_b \quad (12.15.6.2-1)$$

where:

- ε_f = factored long-term strain due to flexure, determined in accordance with Eq. 12.12.3.10.2b-3 as modified below (in./in.)
- ϕ_f = resistance factor for flexure, as defined in Table 12.5.5-1
- S_b = long-term ring-bending strain, as defined in Article 12.15.3.2

The variable Δ_f in Eq. 12.12.3.10.2b-3 shall be set to Δ_A , as specified in Article 12.15.4.

12.15.6.3—Global Buckling

Loads to be considered for global buckling of fiberglass culverts shall include hydrostatic groundwater, soil pressure, and live loads. Factored buckling strain demand shall satisfy:

$$\varepsilon_{fb} \leq \phi_{bck} \varepsilon_{bck} \quad (12.15.6.3-1)$$

in which:

$$\varepsilon_{fb} = \frac{(\gamma_{WA} \eta_{EV} H_w \gamma_w / 144 + \gamma_{EV} \eta_{EV} P_{sp} R_w + \gamma_{LL} \eta_{LL} C_L P_L) R}{1,000 E_{cf} A_g} \quad (12.15.6.3-2)$$

in which:

$$R_w = 1 - 0.33 \frac{H_w}{H} \text{ for } 0 \leq H_w \leq H \quad (12.15.6.3-3)$$

where:

- ε_{fb} = factored buckling strain demand (in./in.)
- ϕ_{bck} = resistance factor for global buckling, as defined in Table 12.5.5-1
- ε_{bck} = nominal strain capacity for general buckling, determined in accordance with Eq. 12.12.3.10.1e-2 as modified below (in./in.)
- γ_{WA} = load factor for hydrostatic pressure
- η_{EV} = load modifier for vertical earth pressure on buried structures, from Article 1.3.2 applied in accordance with Article 12.5.4
- H_w = height of water over top of pipe (ft)
- γ_w = unit weight of water (lb/ft³)

γ_{EV}	=	load factor for vertical earth pressure
P_{sp}	=	soil prism pressure, EV, evaluated at the crown of the pipe determined as the unit weight of soil multiplied by the soil cover depth (psi)
R_w	=	water buoyancy factor
γ_{LL}	=	load factor for live load
η_{LL}	=	load modifier for live load on buried structures, from Article 1.3.2 applied in accordance with Article 12.5.4
C_L	=	live load distribution coefficient, as specified in Article 12.12.3.5
P_L	=	service live load on pipe, as specified in Article 12.6.1 (psi)
R	=	radius of pipe to centroid of pipe wall (in.)
E_{cf}	=	circumferential flexural modulus, as defined in Article 12.15.3.1 (ksi)
A_g	=	area of fiber-reinforced wall of the pipe per unit length, determined from reinforced wall thickness measurements (in. ² /in.)
H	=	height of fill above top of pipe (ft)

The variables E_p and A_{eff} in Eq. 12.12.3.10.1e-2 shall be replaced with E_{cf} and A_g , respectively.

12.15.6.4—Flexibility Limit

The flexibility factor for fiberglass pipe shall be determined in accordance with Article 12.12.3.6, but with the variable E in Eq. 12.12.3.6-1 set to E_{cf} , as defined in Article 12.15.3.1. The flexibility factor shall be limited as specified in Article 12.5.6.3.

12.15.7—Construction and Installation

The contract documents shall require that the construction and installation conform to Section 30 of the *AASHTO LRFD Bridge Construction Specifications*.

Thickness (in.)	Bolt Diameter (in.)	Steel Bolts 5.5 Bolts per ft (kip/ft)	Aluminum Bolts 5.5 Bolts per ft (kip/ft)
0.100	$\frac{3}{4}$	28.0	26.4
0.125	$\frac{3}{4}$	41.0	34.8
0.150	$\frac{3}{4}$	54.1	44.4
0.175	$\frac{3}{4}$	63.7	52.8
0.200	$\frac{3}{4}$	73.4	52.8
0.225	$\frac{3}{4}$	83.2	52.8
0.250	$\frac{3}{4}$	93.1	52.8

Table A12-9—Mechanical Properties for Spiral Rib and Corrugated Metal Pipe and Pipe Arch

Material	Minimum Tensile Strength, F_u (ksi)	Minimum Yield Stress, F_y (ksi)	Modulus of Elasticity, E_m (ksi)
Aluminum H34 ^{(1)&(4)}	31.0	24.0	10,000
Aluminum H32 ^{(2)&(4)}	27.0	20.0	10,000
Steel ⁽³⁾	45.0	33.0	29,000

1. Shall meet the requirements of AASHTO M 197 (ASTM B744), for Alclad Alloy 3004-H34
2. Shall meet the requirements of AASHTO M 197 (ASTM B744), for Alclad Alloy 3004-H32
3. Shall meet the requirements of AASHTO M 167M/M 167 (ASTM A761/A761M), M 218, and M 246 (ASTM A742)
4. H34 temper material shall be used with riveted pipe to achieve seam strength. Both H32 and H34 temper material may be used with helical pipe

Table A12-10—Mechanical Properties—Corrugated Aluminum and Steel Plate

Material	Minimum Tensile Strength (ksi)	Minimum Yield Stress (ksi)	Modulus of Elasticity (ksi)
Aluminum ⁽¹⁾ Plate Thickness (in.)			
0.100–0.175	35.0	24.0	10,000
0.176–0.250	34.0	24.0	10,000
Steel ⁽²⁾ Plate Thickness (in.)			
All	45.0	33.0	29,000
Steel Deep Corrugated Plate	55.0	44.0	29,000

1. Shall meet the requirements of AASHTO M 219 (ASTM B746), Alloy 5052
2. Shall meet the requirements of AASHTO M 167M/M 167 (ASTM A761/A761M)

Table A12-11—PE Corrugated Pipes (AASHTO M 294)

Nominal Size (in.)	Min. ID (in.)	Max. OD (in.)	Min. A (in. ² /ft)	Min. c (in.)	Min. I (in. ⁴ /in.)
12	11.8	14.7	1.5	0.35	0.024
15	14.8	18.0	1.9	0.45	0.053
18	17.7	21.5	2.3	0.50	0.062
24	23.6	28.7	3.1	0.65	0.116
30	29.5	36.4	3.9	0.75	0.163
36	35.5	42.5	4.5	0.90	0.222
42*	41.5	48.0	4.69	1.11	0.543
48*	47.5	55.0	5.15	1.15	0.543

* For the 42.0-in. and 48.0-in. pipe, the wall thickness should be designed using the long-term tensile strength provision, i.e., 900 psi, until new design criteria are established in the AASHTO bridge and structures specifications.

Table A12-12—PE Ribbed Pipes (ASTM F894)

0.280	7/8	197,000 ^a
0.319	7/8	218,000 ^a
0.380	7/8	267,000 ^a

^a The number of bolts per corrugation includes the bolts in the corrugation crest, tangent, and valley; the number of bolts within one pitch. The ultimate seam strengths listed are based on tests of staggered seams in assemblies fabricated from panels with a nominal width of 40.0 in. and include the contribution of additional bolts at the stagger. The ultimate seam strengths listed are only applicable for panels with a nominal width of 40.0 in. and staggered seams.

^b Seam strengths determined based on tests on specimens with three corrugation widths.

Note: The listed ultimate seam strengths are only applicable for panels with a nominal width of 30.0 in. and with staggered seams. The number of bolts per corrugation includes bolts within one pitch: those in the corrugation crest and in the corrugation valley. The ultimate seam strengths listed are based on tests of staggered seams in assemblies fabricated from panels with a nominal width of 30.0 in. and include the contribution of additional bolts at the stagger.

RAILINGS

13.1—SCOPE

A process for the design of crash test specimens to determine their crashworthiness is described in Appendix A13. This methodology is based on an application of the yield line theory. For use beyond the design of test specimens with expected failure modes similar to those shown in Figures CA13.3.1-1 and CA13.3.1-2, a rigorous yield line solution or a finite element solution should be developed. The procedures of Appendix A13 are not applicable to traffic railings mounted on rigid structures, such as retaining walls or spread footings, when the cracking pattern is expected to extend to the supporting components.

With the finite resources available to bridge owners, it is not reasonable to expect all existing rails to be updated any more than to expect every existing building to be immediately updated with the passing of a new building code. Many existing bridge rails have proven functional and need only be replaced when removed for bridge widenings.

Crashworthy—A system that has been successfully crash-tested to a currently acceptable crash test matrix and test level or one that can be geometrically and structurally evaluated as equal to a crash-tested system.

Design Force—An equivalent static force that represents the dynamic force imparted to a railing system by a specified vehicle impacting a railing at a designated speed and angle.

Encroachment—An intrusion into prescribed, restrictive, or limited areas of a highway system, such as crossing a traffic lane or impacting a barrier system. Also, the occupancy of highway right-of-way by nonhighway structures or objects of any kind or character.

End Zone—The area adjacent to any open joint in a concrete railing system that requires added reinforcement.

Expressway—A controlled access arterial highway that may or may not be divided or have grade separations at intersections.

Face of the Curb—The vertical or sloping surface on the roadway side of the curb.

Freeway—A controlled access divided arterial highway with grade separations at intersections.

Longitudinal Loads—Horizontal design forces that are applied parallel to the railing or barrier system and that result from friction on the transverse loads.

Multiple-Use Railing—Railing that may be used either with or without a raised sidewalk.

Owner—An authority or governmental department representing investors and/or taxpayers that is responsible for all the safety design features and functions of a bridge.

Pedestrian Railing—A railing or fencing system, as illustrated in Figure 13.8.2-1, providing physical guidance for pedestrians across a bridge so as to minimize the likelihood of a pedestrian falling over the system.

Post—A vertical or sloping support member of a rail system that anchors a railing element to the deck.

Rail Element—Any component that makes up a railing system. It usually pertains to a longitudinal member of the railing.

Severity—A characterization of the degree of an event. It is usually associated with characterizing accidents as fatal, injury, or property damage only so that a dollar value can be assessed for economic study. It may also pertain to indexing the intensity of an accident so that a railing system can be assessed as a preventive or safety measure.

Speeds—Low/High—Vehicle velocities in mph. Low speeds are usually associated with city or rural travel where posted speeds do not exceed 45 mph. High speeds are usually associated with expressways or freeways where posted speeds are in excess of 45 mph.

Traffic Railing—Synonymous with vehicular railing; used as a bridge- or structure-mounted railing, rather than a guardrail or median barrier as in other publications.

Transverse Loads—Horizontal design forces that are applied perpendicular to a railing or barrier system.

Vehicle Rollover—A term used to describe an accident in which a vehicle rotates at least 90° about its longitudinal axis after contacting a railing. This term is used if the vehicle rolls over as a result of contacting a barrier and not another vehicle.

Warrants—A document that provides guidance to the Designer in evaluating the potential safety and operational benefits of traffic control devices or features. Warrants are not absolute requirements; rather, they are a means of conveying concern over a potential traffic hazard.

13.3—NOTATION

A_f	=	area of post compression flange (in. ²) (A13.4.3.2)
B	=	out-to-out wheel spacing on an axle (ft); distance between centroids of tensile and compressive stress resultants in post (in.) (A13.2) (A13.4.3.2)
b	=	length of deck resisting post strength or shear load (ft) (A13.4.3.1)

C	=	vertical post capacity or compression flange resistance of post in bending (kip-ft) (CA13.4.3.2)
d_b	=	distance from the outer edge of the base plate to the innermost row of bolts (in.) (A13.4.3.1)
E	=	distance from edge of slab to centroid of compressive stress resultant in post (in.) (A13.4.3.2)
F_L	=	longitudinal friction force along rail = $0.33 F_t$ (kips) (A13.2)
F_t	=	transverse vehicle impact force distributed over a length L_t at a height H_e above bridge deck (kips) (A13.2)
F_v	=	vertical force of vehicle laying on top of rail (kips) (A13.2)
F_y	=	yield strength of post-compression flange (ksi) (A13.4.3.2)
f'_c	=	28-day compressive strength of concrete (ksi) (A13.4.3.2)
G	=	height of vehicle center of gravity above bridge deck (in.) (A13.2)
H	=	height of wall (ft) (A13.3.1)
H_R	=	height of rail (ft) (A13.3.3)
H_w	=	height of wall (ft) (A13.3.3)
h	=	depth of slab (in.) (A13.4.3.2)
L	=	post spacing of single span (ft) (A13.3.2)
L_c	=	critical length of wall failure (ft) (A13.3.1)
L_L	=	longitudinal length of distribution of friction force F_L , $L_L = L_t$ (ft) (A13.2)
L_t	=	longitudinal length of distribution of impact force F_t along the railing located a height of the H_e above the deck (ft) (A13.2)
L_v	=	longitudinal distribution of vertical force F_v on top of railing (ft) (A13.2)
ℓ	=	length of vehicle impact load on railing or barrier taken as L_b , L_v , or L_L , as appropriate (ft) (A13.3.1)
M_b	=	ultimate moment capacity of beam at top of wall (kip-ft) (A13.3.1)
M_c	=	ultimate flexural resistance of wall about horizontal axis (kip-ft/ft) (A13.3.1)
M_d	=	deck overhang moment (kip-ft/ft) (A13.4.3.1)
M_p	=	plastic or yield line resistance of rail (kip-ft) (A13.3.2)
M_{post}	=	plastic moment resistance of a single post (kip-ft) (A13.3.2)
M_w	=	ultimate flexural resistance of wall about vertical axis (kip-ft) (A13.3.1)
P_p	=	shear force on a single post which corresponds to M_{post} and is located $\bar{Y}$ above the deck (kips) (A13.3.2)
R	=	total ultimate resistance, i.e., nominal resistance, of the railing (kips) (A13.3.2)
R_R	=	ultimate capacity of rail over one span (kips) (A13.3.3)
R'_R	=	ultimate transverse resistance of rail over two spans (kips) (A13.3.3)
R_w	=	total transverse resistance of the railing (kips); ultimate capacity of wall as specified in Article A13.3.1 (kips) (A13.3.1) (A13.3.3)
R'_w	=	capacity of wall, reduced to resist post load (kips) (A13.3.3)
$\bar{R}$	=	sum of horizontal components of rail strengths (kips) (A13.2)
T	=	tensile force per unit of deck length (kip/ft) (A13.4.2)
v_c	=	nominal shear resistance provided by tensile stresses in the concrete (ksi) (A13.4.3.2)
V_n	=	nominal shear resistance of the section considered (kips) (A13.4.3.2)
V_r	=	factored shear resistance (kips) (A13.4.3.2)
V_u	=	factored shear force at section (kips) (A13.4.3.2)
W	=	weight of vehicle corresponding to the required test level, from Table 13.7.2-1 (kips) (13.7.2)
W_b	=	width of base plate (in.) (A13.4.3.1)
X	=	length of overhang from face of support to exterior girder or web (ft) (A13.4.3.1)
$\bar{Y}$	=	height of $\bar{R}$ above bridge deck (in.) (A13.2)
β_c	=	ratio of the long side to the short side of the concentrated load or reaction area (A13.4.3.2)
ϕ	=	resistance factor = 1.0 (A13.4.3.2)

13.4—GENERAL

The owner shall develop the warrants for the bridge site. A bridge railing should be chosen to satisfy the concerns of the warrants as completely as possible and practical.

Railings shall be provided along the edges of structures for protection of traffic and pedestrians. Other applications may be warranted on bridge-length culverts.

A pedestrian walkway may be separated from an adjacent roadway by a barrier curb, traffic railing, or

C13.4

Additional guidance applicable to bridge-length culverts may be found in the AASHTO *Roadside Design Guide*.

The following guidelines indicate the application of various types of rails:

combination railing, as indicated in Figure 13.4-1. On high-speed urban expressways where a pedestrian walkway is provided, the walkway area shall be separated from the adjacent roadway by a traffic railing or combination railing.

Figure 13.4-1—Pedestrian Walkway

New bridge railings and the attachment to the deck overhang shall satisfy crash testing requirements to confirm that they meet the structural and geometric requirements of a specified railing test level using the test criteria specified in Article 13.7.2.

13.5—MATERIALS

The requirements of Sections 5, 6, 7, and 8 shall apply to the materials employed in a railing system, unless otherwise modified herein.

- Traffic railing is used when a bridge is for the exclusive use of highway traffic;
- A combination barrier in conjunction with a raised curb and sidewalk is used only on low-speed highways;
- On high-speed highways, the pedestrian or bicycle path should have both an outboard pedestrian or bicycle railing and an inboard combination railing; and
- Separate pedestrian bridges should be considered where the amount of pedestrian traffic or other risk factors so indicate.

For the purpose of this Article, low speed may be taken as speeds up to and including 45 mph. High speed may be taken as speeds in excess of 45 mph.

The walkway faces of combination railings separating walkways from adjacent roadways serve as pedestrian or bicycle railings. When the height of such railings above the walkway surface is less than the minimum height required for pedestrian or bicycle railings, as appropriate, the Designer may consider providing additional components, such as metal rails, on top of the combination railing. The additional components need to be designed for the appropriate pedestrian or bicycle railing design forces.

Warning devices for pedestrians are beyond the scope of these Specifications, but they should be considered.

Procedures for testing railings are given in MASH.

C13.5

Factors to be considered in choosing the material for use in any railing system include ultimate strength, durability, ductility, maintenance, ease of replacement, and long-term behavior.

13.6—LIMIT STATES AND RESISTANCE FACTORS

13.6.1—Strength Limit State

The strength limit states shall apply using the applicable load combinations in Table 3.4.1-1 and the loads specified herein. The resistance factors for post and railing components shall be as specified in Articles 5.5.4, 6.5.4, 7.5.4, and 8.5.2.

Design loads for pedestrian railings shall be as specified in Article 13.8.2. Design loads for bicycle railings shall be as specified in Article 13.9.3. Pedestrian or bicycle loadings shall be applied to combination railings as specified in Article 13.10.3. Deck overhangs shall be designed for applicable strength load combinations specified in Table 3.4.1-1.

13.6.2—Extreme Event Limit State

The forces to be transmitted from the bridge railing to the bridge deck may be determined from an ultimate strength analysis of the railing system using the loads given in Appendix A13. Those forces shall be considered to be the factored loads at the extreme event limit state.

13.7—TRAFFIC RAILINGS

13.7.1—Railing System

13.7.1.1—General

The primary purpose of traffic railings shall be to contain and redirect vehicles using the structure. All new vehicle traffic barrier systems, traffic railings, and combination railings shall be shown to be structurally and geometrically crashworthy.

Consideration should be given to:

- Protection of the occupants of a vehicle in collision with the railing,
- Protection of other vehicles near the collision,
- Protection of persons and property on roadways and other areas underneath the structure,
- Possible future rail upgrading,
- Railing cost-effectiveness, and
- Appearance and freedom of view from passing vehicles.

A combination railing, conforming to the dimensions given in Figures 13.8.2-1 and 13.9.3-1, and crash tested with a sidewalk may be considered acceptable for use with sidewalks having widths 3.5 ft or greater and curb heights up to the height used in the crash test installation.

A railing designed for multiple use shall be shown to be crashworthy with or without the sidewalk. Use of the combination vehicle-pedestrian railing shown in Figure 13.7.1.1-1 shall be restricted to roads designated for 45 mph or less and need to be tested to Test Level 1 or 2.

C13.7.1.1

Variations in traffic volume, speed, vehicle mix, roadway alignment, activities, and conditions beneath a structure, and other factors combine to produce a vast variation in traffic railing performance requirements.

Because of more recent tests on sidewalks, an 8.0-in. maximum height for sidewalk curbs has generally been accepted.

AASHTO's *A Policy on Geometric Design of Highways and Streets* recommends that a barrier curb be

Figure 13.7.1.1-1—Typical Raised Sidewalk

13.7.1.2—Approach Railings

An approach guardrail system should be provided at the beginning of all bridge railings in high-speed rural areas.

A bridge approach railing system should include a transition from the guardrail system to the rigid bridge railing system that is capable of providing lateral resistance to an errant vehicle. The approach guardrail system shall have a crashworthy end terminal at its nosing.

13.7.1.3—End Treatment

In high-speed rural areas, the approach end of a parapet or railing shall have a crashworthy configuration or be shielded by a crashworthy traffic barrier.

13.7.2—Test Level Selection Criteria

One of the following test levels should be specified:

- TL-1—Test Level One—taken to be generally acceptable for work zones with low posted speeds and very low-volume, low-speed local streets;
- TL-2—Test Level Two—taken to be generally acceptable for work zones and most local and collector roads with favorable site conditions as well as where a small number of heavy vehicles is expected and posted speeds are reduced;

used only for speeds of 45 mph or less. For speeds of 50 mph or greater, pedestrians should be protected by a separation traffic barrier.

A railing intended for use only on a sidewalk need not be tested without the sidewalk.

C13.7.1.2

In urban areas or where city streets and/or sidewalks prevent installation of approach guardrail transitions or crashworthy terminals, consideration should be given to:

- Extending the bridge rail or guard rail in a manner that prevents encroachment of a vehicle onto any highway system below the bridge,
- Providing a barrier curb,
- Restricting speed,
- Adding signing of intersections, and
- Providing recovery areas.

A bridge end drainage facility should be an integral part of the barrier transition design.

C13.7.1.3

If the approach railing is connected to a side-of-road railing system, it can be continuous with the bridge approach system, and only a transition from a flexible to a rigid railing system is required.

C13.7.2

The six test levels mentioned herein are intended to correspond with the six test levels contained in AASHTO's *Manual for Assessing Safety Hardware* and NCHRP Report 350, *Recommended Procedures for the Safety Performance Evaluation of Highway Features*. AASHTO's *A Policy on Geometric Design of Highways and Streets* and its *Roadside Design Guide* are referred to as aids in the bridge railing selection process.

The individual tests are designed to evaluate one or more of the principal performance factors of the bridge railing, which include structural adequacy, occupant risk,

- TL-3—Test Level Three—taken to be generally acceptable for a wide range of high-speed arterial highways with very low mixtures of heavy vehicles and with favorable site conditions;
- TL-4—Test Level Four—taken to be generally acceptable for the majority of applications on high-speed highways, freeways, expressways, and Interstate highways with a mixture of trucks and heavy vehicles;
- TL-5—Test Level Five—taken to be generally acceptable for the same applications as TL-4 and where large trucks make up a significant portion of the average daily traffic or when unfavorable site conditions justify a higher level of rail resistance; and
- TL-6—Test Level Six—taken to be generally acceptable for applications where tanker-type trucks or similar high center of gravity vehicles are anticipated, particularly along with unfavorable site conditions.

It shall be the responsibility of the user agency to determine which of the test levels is most appropriate for the bridge site.

The testing criteria for the chosen test level shall correspond to vehicle weights and speeds and angles of impact outlined in Table 13.7.2-1.

and postimpact behavior of the test vehicle. In general, the lower test levels are applicable for evaluating and selecting bridge railings to be used on segments of lower service level roadways and certain types of work zones. The higher test levels are applicable for evaluating and selecting bridge railings to be used on higher service level roadways or at locations that demand a special, high-performance bridge railing. In this regard, TL-4 railings are expected to satisfy the majority of interstate design requirements.

TL-5 provides for a van-type tractor-trailer that will satisfy design requirements where TL-4 railings are deemed to be inadequate due to the high number of this type of vehicle anticipated, or due to unfavorable site conditions where rollover or penetration beyond the railing could result in severe consequences.

TL-6 provides for a tanker-type truck that will satisfy design requirements where this type vehicle with a higher center of gravity has shown a history of rollover or penetration, or unfavorable site conditions may indicate the need for this level of rail resistance.

Unfavorable site conditions include but are not limited to reduced radius of curvature, steep downgrades on curvature, variable cross slopes, and adverse weather conditions.

Agencies should develop objective guidelines for use of bridge railings. These guidelines should take into account factors such as traffic conditions, traffic volume and mix, cost and in-service performance, and life-cycle cost of existing railings.

These criteria, including other vehicle characteristics and tolerances, are described in detail in MASH and NCHRP Report 350.

Table 13.7.2-1—Bridge Railing Test Levels and Crash Test Criteria

	Vehicle Characteristics	Small Automobiles		Pickup Truck	Single-Unit Van Truck	Van-Type Tractor-Trailer		Tractor-Tanker Trailer

13.7.3—Railing Design

13.7.3.1—General

A traffic railing should normally provide a smooth, continuous face of rail on the traffic side. Steel posts with rail elements should be set back from the face of the rail. Structural continuity in the rail members and anchorages of ends should be considered.

A railing system and its connection to the deck shall be approved only after they have been shown through crash testing to be satisfactory for the desired test level.

13.7.3.1.1—Application of Previously Tested Systems

A crashworthy railing system may be used without further analysis and/or testing, provided that the proposed installation does not have features that are absent in the tested configuration and that might detract from the performance of the tested railing system.

C13.7.3.1

Protrusions or depressions at rail openings may be acceptable, provided that their thickness, depth, or geometry does not prevent the railing from meeting the crash test evaluation criteria.

Test specimens should include a representative length of the overhang to account for the effect of deck flexibility on the distance over which the railing engages the deck.

C13.7.3.1.1

When a minor detail is changed on or an improvement is made to a railing system that has already been tested and approved, engineering judgment and analysis should be used when determining the need for additional crash testing.

13.7.3.1.2—New Systems

New railing systems may be used, provided that acceptable performance is demonstrated through full-scale crash tests.

The crash test specimen for a railing system may be designed to resist the applied loads in accordance with Appendix A13.

Provision shall be made to transfer loads from the railing system to the deck. Railing loads may be taken from Appendix A13.

Unless a lesser thickness can be proven satisfactory during the crash testing procedure, the minimum edge thickness for concrete deck overhangs shall be taken as:

- For concrete deck overhangs supporting a deck-mounted post system: 8.0 in.
- For a side-mounted post system: 12.0 in.
- For concrete deck overhangs supporting concrete parapets or barriers: 8.0 in.

13.7.3.2—Height of Traffic Parapet or Railing

Traffic railings shall be at least 27.0 in. for TL-3, 32.0 in. for TL-4, 42.0 in. for TL-5, and 90.0 in. in height for TL-6.

The bottom 3.0-in. lip of the safety shape shall not be increased for future overlay considerations.

The minimum height for a concrete parapet with a vertical face shall be 27.0 in. The height of other combined concrete and metal rails shall not be less than 27.0 in. and shall be determined to be satisfactory through crash testing for the desired test level.

The minimum height of a pedestrian or bicycle railing should be measured above the surface of the sidewalk or bikeway.

The minimum geometric requirements for combination railings beyond those required to meet crash test requirements shall be taken as specified in Articles 13.8, 13.9, and 13.10.

13.8—PEDESTRIAN RAILINGS**13.8.1—Geometry**

The minimum height of a pedestrian railing shall be 42.0 in., measured from the top of the walkway.

A pedestrian railing may be composed of horizontal and/or vertical elements. The clear opening between elements shall be such that a 6.0-in. diameter sphere shall not pass through.

When both horizontal and vertical elements are used, the 6.0-in. clear opening shall apply to the lower 27.0 in. of the railing, and the spacing in the upper portion shall be such that an 8.0-in. diameter sphere shall not pass through. A safety toe rail or curb should be provided. Rails should project beyond the face of posts, pickets, or both as shown in Figure A13.1.1-2.

C13.7.3.1.2

Preliminary design for bridge decks should comply with Article A13.1.2. A determination of the adequacy of deck reinforcement for the distribution of post anchorage loads to the deck should be made during the rail testing program. If the rail testing program satisfactorily models the bridge deck, damage to the deck edge can be assessed at this time.

In adequately designed bridge deck overhangs, the major crash-related damage presently occurs in short sections of slab areas where the barrier is hit.

C13.7.3.2

These heights have been determined as satisfactory through crash tests performed in accordance with NCHRP Report 350 and experience.

For future deck overlays, an encroachment of 2.0 in., leaving a 1.0-in. lip, has been satisfactorily tested for safety shapes.

C13.8.1

The rail spacing requirements given above should not apply to chain link or metal fabric fence support rails and posts. Mesh size in chain link or metal fabric fence should have openings no larger than 2.0 in.

13.8.2—Design Loads

The design live load for pedestrian railings shall be taken as $w = 0.050$ klf, both transversely and vertically, acting simultaneously. In addition, each longitudinal element will be designed for a concentrated load of 0.20 kips, which shall act simultaneously with the above loads at any point and in any direction at the top of the longitudinal element.

The posts of pedestrian railings shall be designed for a concentrated design live load applied transversely at the center of gravity of the upper longitudinal element or, for railings with a total height greater than 5.0 ft, at a point 5.0 ft above the top surface of the sidewalk. The value of the concentrated design live load for posts, P_{LL} , in kips, shall be taken as:

$$P_{LL} = 0.20 + 0.050L \quad (13.8.2-1)$$

where:

L = post spacing (ft)

The application of loads shall be as indicated in Figure 13.8.2-1, in which the shapes of rail members are illustrative only. Any material or combination of materials specified in Article 13.5 may be used.

Figure 13.8.2-1—Pedestrian Railing Loads—To be used on the outer edge of a sidewalk when highway traffic is separated from pedestrian traffic by a traffic railing. Railing shape illustrative only.

The design wind load for chain link or metal fabric fence shall be taken as 0.015 ksf acting normal to the entire surface. The wind load need not be applied simultaneously with live load.

The size of openings should be capable of retaining an average size beverage container.

C13.8.2

These live loads apply to the railing. The pedestrian live load, specified in Article 3.6.1.6, applies to the sidewalk.

13.9—BICYCLE RAILINGS

13.9.1—General

Bicycle railings shall be used on bridges specifically designed to carry bicycle traffic and on bridges where specific protection of bicyclists is deemed necessary.

13.9.2—Geometry

The height of a bicycle railing shall not be less than 42.0 in., measured from the top of the riding surface.

Bicycle railings shall have rail spacing satisfying the respective provisions of Article 13.8.1.

If deemed necessary, rubrails attached to the rail or fence to prevent snagging should be deep enough to protect a wide range of bicycle handlebar heights.

If screening, fencing, or a solid face is utilized, the number of rails may be reduced.

13.9.3—Design Live Loads

If the rail height exceeds 54.0 in. above the riding surface, design loads shall be determined by the Designer. The design loads for the lower 54.0 in. of the bicycle railing shall not be less than those specified in Article 13.8.2, except that for railings with total height greater than 54.0 in., the design live load for posts shall be applied at a point 54.0 in. above the riding surface.

The application of loads shall be as indicated in Figure 13.9.3-1. Any material or combination of materials specified in Article 13.5 may be used.

C13.9.2

Railings, fences, or barriers on either side of a shared use path on a structure, or along bicycle lane, shared use path or signed shared roadway located on a highway bridge should be a minimum of 42.0 in. high. The 42.0-in. minimum height is in accordance with the *AASHTO Guide for the Development of Bicycle Facilities*.

On a bridge or bridge approach where high-speed, high-angle impacts with a railing, fence, or barrier are more likely to occur (such as short-radius curves with restricted sight distance, or at the end of a long descending grade) or in locations with site-specific safety concerns, a railing, fence, or barrier height above the minimum should be considered.

The need for rubrails attached to a rail or fence is controversial among many bicyclists.

Figure 13.9.3-1—Bicycle Railing Loads—To be used on the outer edge of a bikeway when highway traffic is separated from bicycle traffic by a traffic railing. Railing shape illustrative only.

13.10—COMBINATION RAILINGS

13.10.1—General

The combination railing shall conform to the requirements of either the pedestrian or bicycle railings, as specified in Articles 13.8 and 13.9, whichever is applicable. The traffic railing portion of the combination railing shall conform to Article 13.7.

13.10.2—Geometry

The geometric provisions of Articles 13.7, 13.8, and 13.9 shall apply to their respective portions of a combination railing.

13.10.3—Design Live Loads

Design loads, specified in Articles 13.8 and 13.9, shall not be applied simultaneously with the vehicular impact loads.

13.11—CURBS AND SIDEWALKS

13.11.1—General

Horizontal measurements of roadway width shall be taken from the bottom of the face of the curb. A sidewalk curb located on the highway traffic side of a bridge railing shall be considered an integral part of the railing and shall be subject to the crash test requirements specified in Article 13.7.

13.11.2—Sidewalks

When curb and gutter sections with sidewalks are used on roadway approaches, the curb height for raised sidewalks on the bridge should be no more than 8.0 in. If a barrier curb is required, the curb height should not be less than 6.0 in. If the height of the curb on the bridge differs from that off the bridge, it should be uniformly transitioned over a distance greater than or equal to 20 times the change in height.

13.11.3—End Treatment of Separation Railing

The end treatment of any traffic railing or barrier shall meet the requirements specified in Articles 13.7.1.2 and 13.7.1.3.

C13.11.2

Raised sidewalks on bridges are not usually provided where the approach roadway is not curbed for pedestrians or the structure is not planned for pedestrian occupancy.

For recommendations on sidewalk width, see Figure 13.7.1.1-1 and AASHTO's *A Policy on Geometric Design of Highways and Streets*.

During stage construction, the same transition considerations will be given to the provision of ramps from the bridge sidewalk to the approach surface.

APPENDIX A13

A13.1—GEOMETRY AND ANCHORAGES

A13.1.1—Separation of Rail Elements

For traffic railings, the criteria for maximum clear opening below the bottom rail, c_b , the setback distance, S , and maximum opening between rails, c , shall be as follows:

- The rail contact widths for typical railings may be taken as illustrated in Figure A13.1.1-1;
- The total width of the rail(s) in contact with the vehicle, ΣA , shall not be less than 25 percent of the height of the railing;
- For post railings, the vertical clear opening, c , and the post setback, S , shall be within or below the shaded area shown in Figure A13.1.1-2; and
- For post railings, the combination of $(\Sigma A/H)$ and the post setback, S , shall be within or above the shaded area shown in Figure A13.1.1-3.

CA13.1.1

The post setback shown from face of rail for various post shapes is based on a limited amount of crash test data. The potential for wheel snagging involved with a given design should be evaluated as part of the crash test program.

The post setback, S , shown for various shape posts in Figure A13.1.1-2, recognizes the tendency for various shape posts to snag wheels. The implication of the various definitions of setback, S , is that all other factors being equal, the space between a rail and the face of a rectangular post will be greater than the distance between a rail and the face of a circular post.

Figure A13.1.1-1—Typical Traffic Railings

Figure A13.1.1-2—Potential for Wheel, Bumper, or Hood Impact with Post

Figure A13.1.1-3—Post Setback Criteria

The maximum clear vertical opening between succeeding rails or posts shall be as specified in Articles 13.8, 13.9, and 13.10.

A13.1.2—Anchorages

The yield strength of anchor bolts for steel railings shall be fully developed by bond, hooks, attachment to embedded plates, or any combination thereof.

Reinforcing steel for concrete barriers shall have embedment length sufficient to develop the yield strength.

A13.2—TRAFFIC RAILING DESIGN FORCES

Unless modified herein, the extreme event limit state and the corresponding load combinations in Table 3.4.1-1 shall apply.

Railing design forces and geometric criteria to be used in developing test specimens for a crash test program should be taken as specified in Table A13.2-1 and illustrated in Figure A13.2-1. The transverse and longitudinal loads given in Table A13.2-1 need not be applied in conjunction with vertical loads.

The effective height of the vehicle rollover force is taken as:

$$H_e = G - \frac{12WB}{2F_t} \quad (\text{A13.2-1})$$

where:

- G = height of vehicle center of gravity above bridge deck, as specified in Table 13.7.2-1 (in.)
- W = weight of vehicle corresponding to the required test level, as specified in Table 13.7.2-1 (kips)
- B = out-to-out wheel spacing on an axle, as specified in Table 13.7.2-1 (ft)
- F_t = transverse force corresponding to the required test level, as specified in Table A13.2-1 (kips)

Railings shall be proportioned such that:

$$\bar{R} \geq F_t \quad (\text{A13.2-2})$$

$$\bar{Y} \geq \frac{H_e}{12} \quad (\text{A13.2-3})$$

in which:

$$\bar{R} = \sum R_i \quad (\text{A13.2-4})$$

$$\bar{Y} = \frac{\sum (R_i Y_i)}{\bar{R}} \quad (\text{A13.2-5})$$

CA13.1.2

Noncorrosive bonding agents for anchor dowels may be cement grout, epoxy, or a magnesium phosphate compound. Sulfur or expansive-type grouts should not be used.

Some bonding agents on the market have corrosive characteristics; these should be avoided.

Development length for reinforcing bars is specified in Section 5.

CA13.2

Nomenclature for Eqs. A13.2-1 and A13.2-2 is illustrated in Figure CA13.2-1.

Figure CA13.2-1—Traffic Railing

If the total resistance, $\bar{R}$, of a post-and-beam railing system with multiple rail elements is significantly greater than the applied load, F_t , then the resistance, R_i , for the lower rail element(s) used in calculations may be reduced.

The reduced value of $\bar{R}$ will result in an increase in the computed value of $\bar{Y}$. The reduced notional total rail resistance and its effective height must satisfy Eqs. A13.2-2 and A13.2-3.

where:

R_i = resistance of the rail (kips)

Y_i = distance from bridge deck to the i th rail (ft)

All forces shall be applied to the longitudinal rail elements. The distribution of longitudinal loads to posts shall be consistent with the continuity of rail elements. Distribution of transverse loads shall be consistent with the assumed failure mechanism of the railing system.

Eq. A13.2-1 has been found to give reasonable predictions of effective railing height requirements to prevent rollover.

If the design load located at H_e falls between rail elements, it should be distributed proportionally to rail elements above and below such that $Y \geq H_e$.

As an example of the significance of the data in Table A13.2-1, the length of 4.0 ft for L_t and L_L is the length of significant contact between the vehicle and railing that has been observed in films of crash tests. The length of 3.5 ft for TL-4 is the rear-axle tire diameter of the truck. The length of 8.0 ft for TL-5 and TL-6 is the length of the tractor rear tandem axles: two 3.5-ft diameter tires, plus 1.0 ft between them.

F_v , the weight of the vehicle lying on top of the bridge rail, is distributed over the length of the vehicle in contact with the rail, L_v .

For concrete railings, Eq. A13.2-1 results in a theoretically-required height, H , of 34.0 in. for TL-4. However, a height of 32.0 in., shown in Table A13.2-1, was considered to be acceptable because many railings of that height have been built and appear to be performing acceptably.

The minimum height, H , listed for TL-1, TL-2, and TL-3 is based on the minimum railings height used in the past. The minimum effective height, H_e , for TL-1 is an estimate based on the limited information available for this test level.

The minimum height, H , of 42.0 in., shown in Table A13.2-1, for TL-5 is based on the height used for successfully crash-tested concrete barrier engaging only the tires of the truck. For post-and-beam metal bridge railings, it may be prudent to increase the height by 12.0 in. so as to engage the bed of the truck.

The minimum height, H , shown in Table A13.2-1, for TL-6 is the height required to engage the side of the tank as determined by crash test.

Table A13.2-1—Design Forces for Traffic Railings

Design Forces and Designations	Railing Test Levels					
	TL-1	TL-2	TL-3	TL-4	TL-5	TL-6
F_t Transverse (kips)	13.5	27.0	54.0	54.0	124.0	175.0
F_L Longitudinal (kips)	4.5	9.0	18.0	18.0	41.0	58.0
F_v Vertical (kips) Down	4.5	4.5	4.5	18.0	80.0	80.0
L_t and L_L (ft)	4.0	4.0	4.0	3.5	8.0	8.0
L_v (ft)	18.0	18.0	18.0	18.0	40.0	40.0
H_e (min) (in.)	18.0	20.0	24.0	32.0	42.0	56.0
Minimum H Height of Rail (in.)	27.0	27.0	27.0	32.0	42.0	90.0

Figure A13.2-1—Metal Bridge Railing Design Forces, Vertical Location, and Horizontal Distribution Length

A13.3—DESIGN PROCEDURE FOR RAILING TEST SPECIMENS

A13.3.1—Concrete Railings

Yield line analysis and strength design for reinforced concrete and prestressed concrete barriers or parapets may be used.

The nominal railing resistance to transverse load, R_w , may be determined using a yield line approach as:

- For impacts within a wall segment:

$$R_w = \left(\frac{2}{2L_c - L_t} \right) \left(8M_b + 8M_w + \frac{M_c L_c^2}{H} \right) \quad (\text{A13.3.1-1})$$

The critical wall length over which the yield line mechanism occurs, L_c , shall be taken as:

$$L_c = \frac{L_t}{2} + \sqrt{\left(\frac{L_t}{2} \right)^2 + \frac{8H(M_b + M_w)}{M_c}} \quad (\text{A13.3.1-2})$$

- For impacts at end of wall or at joint:

$$R_w = \left(\frac{2}{2L_c - L_t} \right) \left(M_b + M_w + \frac{M_c L_c^2}{H} \right) \quad (\text{A13.3.1-3})$$

$$L_c = \frac{L_t}{2} + \sqrt{\left(\frac{L_t}{2} \right)^2 + H \left(\frac{M_b + M_w}{M_c} \right)} \quad (\text{A13.3.1-4})$$

where:

- F_t = transverse force specified in Table A13.2-1 assumed to be acting at top of a concrete wall (kips)
- H = height of wall (ft)
- L_c = critical length of yield line failure pattern (ft)
- L_t = longitudinal length of distribution of impact force, F_t (ft)

Figure A13.2-1 shows the design forces from Table A13.2-1 applied to a beam and post railing. This is for illustrative purposes only. The forces and distribution lengths shown apply to any type of railing.

CA13.3.1

The yield line analysis shown in Figures CA13.3.1-1 and CA13.3.1-2 includes only the ultimate flexural capacity of the concrete component. Stirrups or ties should be provided to resist the shear and/or diagonal tension forces.

The ultimate flexural resistance, M_s , of the bridge deck or slab should be determined in recognition that the deck is also resisting a tensile force, caused by the component of the impact forces, F_t .

In this analysis, it is assumed that the yield line failure pattern occurs within the parapet only and does not extend into the deck. This means that the deck must have sufficient resistance to force the yield line failure pattern to remain within the parapet. If the failure pattern extends into the deck, the equations for resistance of the parapet are not valid.

The analysis is also based on the assumption that sufficient longitudinal length of parapet exists to result in the yield line failure pattern shown. For short lengths of parapet, a single yield line may form along the juncture of the parapet and deck. Such a failure pattern is permissible, and the resistance of the parapet should be computed using an appropriate analysis.

This analysis is based on the assumption that the negative and positive wall resisting moments are equal and that the negative and positive beam resisting moments are equal.

The measurement of system resistance of a concrete railing is R_w , which is compared to the loads in Table A13.2-1 to determine structural adequacy. The flexure resistances, M_b , M_w , and M_c , are related to the system resistance, R_w , through the yield line analysis embodied in Eqs. A13.3.1-1 and A13.3.1-2. In the terminology of these Specifications, R_w is the nominal resistance because it is compared to the nominal load given in Table A13.2-1.

Where the width of the concrete railing varies along the height, M_c used in Eqs. A13.3.1-1 through A13.3.1-4 for wall resistance should be taken as the average of its value along the height of the railing.

- R_w = total transverse resistance of the railing (kips)
 M_b = additional flexural resistance of beam in addition to M_w , if any, at top of wall (kip-ft)
 M_c = flexural resistance of cantilevered walls about an axis parallel to the longitudinal axis of the bridge (kip-ft/ft)
 M_w = flexural resistance of the wall about its vertical axis (kip-ft)

For use in the above equations, M_c and M_w should not vary significantly over the height of the wall. For other cases, a rigorous yield line analysis should be used.

Figure CA13.3.1-1—Yield Line Analysis of Concrete Parapet Walls for Impact within Wall Segment

Figure CA13.3.1-2—Yield Line Analysis of Concrete Parapet Walls for Impact near End of Wall Segment

A13.3.2—Post-and-Beam Railings

Inelastic analysis shall be used for design of post-and-beam railings under failure conditions. The critical rail nominal resistance, R , when the failure does not involve the end post of a segment, shall be taken as the least value determined from Eqs. A13.3.2-1 and A13.3.2-2 for various numbers of railing spans, N .

CA13.3.2

A basis for applying inelastic analysis is shown in Figure CA13.3.2-1.

Single-Span Failure Mode

Two-Span Failure Mode

Three-Span Failure Mode

Figure CA13.3.2-1—Possible Failure Modes for Post-and-Beam Railings

- For failure modes involving an odd number of railing spans, N :

$$R = \frac{16M_p + (N-1)(N+1)P_p L}{2NL - L_t} \quad (\text{A13.3.2-1})$$

- For failure modes involving an even number of railing spans, N :

$$R = \frac{16M_p + N^2 P_p L}{2NL - L_t} \quad (\text{A13.3.2-2})$$

where:

- L = post spacing or single-span (ft)
- M_p = inelastic or yield line resistance of all of the rails contributing to a plastic hinge (kip-ft)
- M_{post} = plastic moment resistance of a single post (kip-ft)

This design procedure is applicable to concrete and metal post-and-beam railings.

The post on each end of the plastic mechanism must be able to resist the rail or beam shear.

For multiple-rail systems, each of the rails may contribute to the yield mechanism shown schematically in Figure CA13.3.2-1, depending on the rotation corresponding to its vertical position.

- P_p = shear force on a single post which corresponds to M_{post} and is located $\bar{Y}$ above the deck (kips)
 R = total ultimate resistance, i.e., nominal resistance, of the railing (kips)
 L_t, L_L = transverse length of distributed vehicle impact loads, F_t and F_L (ft)

For impact at the end of rail segments that causes the end post to fail, the critical rail nominal resistance, R , shall be calculated using Eq. A13.3.2-3.

- For any number of railing spans, N ,

$$R = \frac{2M_p + 2P_p L \left(\sum_{i=1}^N i \right)}{2NL - L_t} \quad (\text{A13.3.2-3})$$

A13.3.3—Concrete Parapet and Metal Rail

CA13.3.3

The resistance of each component of a combination bridge rail shall be determined as specified in Articles A13.3.1 and A13.3.2. The flexural strength of the rail shall be determined over one span, R_R , and over two spans, R'_R . The resistance of the post on top of the wall, P_p , including the resistance of the anchor bolts or post, shall be determined.

The resistance of the combination parapet and rail shall be taken as the lesser of the resistances determined for the two failure modes shown in Figures A13.3.3-1 and A13.3.3-2.

Figure A13.3.3-1—Concrete Wall and Metal Rail Evaluation—Impact at Midspan of Rail

$$\bar{R} = P_p + R'_R + R'_w \quad (\text{A13.3.3-3})$$

$$\bar{Y} = \frac{P_p H_R + R'_R H_R + R'_w H_w}{\bar{R}} \quad (\text{A13.3.3-4})$$

in which:

$$R'_w = \frac{R_w H_w - P_p H_R}{H_w} \quad (\text{A13.3.3-5})$$

where:

- P_p = ultimate transverse resistance of post (kips)
 R'_R = ultimate transverse resistance of rail over two spans (kips)
 R'_w = capacity of wall, reduced to resist post load (kips)
 R_w = ultimate transverse resistance of wall as specified in Article A13.3.1 (kips)

The analysis herein does not consider impacts near open joints in the concrete wall or parapet. The metal rail will help distribute load across such joints. Improved rail resistance will be obtained if the use of expansion and contraction joints is minimized.

For impact near the end of railing segments, the nominal resistance may be calculated as the sum of the wall resistance, calculated using Eq. A13.3.1-3, and the metal rail resistance over one span, calculated using Eq. A13.3.2-3.

A13.3.4—Wood Barriers

Wood barriers shall be designed by elastic linear analysis with member sections proportioned on the basis of their resistances, specified in Section 8, using the strength limit states and the applicable load combinations specified in Table 3.4.1-1.

CA13.3.4

A limit or failure mechanism is not recommended for wood railings.

A13.4—DECK OVERHANG DESIGN

A13.4.1—Design Cases

Bridge deck overhangs shall be designed for the following design cases considered separately:

- Design Case 1: the transverse and longitudinal forces specified in Table A13.2-1—Extreme Event Load Combination II limit state
 Design Case 2: the vertical forces specified in Table A13.2-1—Extreme Event Load Combination II limit state
 Design Case 3: the loads, specified in Article 3.6.1, that occupy the overhang—Load Combination Strength I limit state

For Design Cases 1 and 2, the load factor for dead load, γ_p , shall be taken as 1.0.

The total factored force effect shall be taken as:

$$Q = \sum \eta_i \gamma_i Q_i \quad (\text{A13.4.1-1})$$

where:

- η_i = load modifier specified in Article 1.3.2
 γ_i = load factors specified in Tables 3.4.1-1 and 3.4.1-2, unless specified elsewhere
 Q_i = force effects from loads specified herein

A13.4.2—Decks Supporting Concrete Parapet Railings

For Design Case 1, the deck overhang may be designed to provide a flexural resistance, M_s , in kip-ft/ft which, acting coincident with the tensile force, T , in kip/ft, specified herein, exceeds M_c of the parapet at its base. The axial tensile force, T , may be taken as:

$$T = \frac{R_w}{L_c + 2H} \quad (\text{A13.4.2-1})$$

where:

- R_w = parapet resistance specified in Article A13.3.1 (kips)
- L_c = critical length of yield line failure pattern (ft)
- H = height of wall (ft)
- T = tensile force per unit of deck length (kip/ft)

Design of the deck overhang for the vertical forces specified in Design Case 2 shall be based on the overhanging portion of the deck.

A13.4.3—Decks Supporting Post-and-Beam Railings**A13.4.3.1—Overhang Design**

For Design Case 1, the moment in kip-ft/ft, M_d , and tensile force, in kip/ft of deck, T , may be taken as:

$$M_d = \frac{12M_{post}}{W_b + d_b} \quad (\text{A13.4.3.1-1})$$

$$T = \frac{12P_p}{W_b + d_b} \quad (\text{A13.4.3.1-2})$$

For Design Case 2, the punching shear force and overhang moment may be taken as:

$$P_v = \frac{F_v L}{L_v} \quad (\text{A13.4.3.1-3})$$

$$M_d = \frac{P_v X}{b} \quad (\text{A13.4.3.1-4})$$

in which:

$$b = 2X + \frac{W_b}{12} \leq L \quad (\text{A13.4.3.1-5})$$

where:

- M_{post} = plastic moment resistance of a single post (kip-ft)
- P_p = shear force on a single post which corresponds to M_{post} and is located $\bar{Y}$ above the deck (kips)

CA13.4.2

If the deck overhang capacity is less than that specified, the yield line failure mechanism for the parapet may not develop as shown in Figure CA13.3.1-1, and Eqs. A13.3.1-1 and A13.3.1-2 will not be correct.

The crash testing program is oriented toward survival, not necessarily the identification of the ultimate strength of the railing system. This could produce a railing system that is significantly overdesigned, leading to the possibility that the deck overhang is also overdesigned.

CA13.4.3.1

Vehicle collision on beam-and-post railing systems, such as a metal system with wide flange or tubular posts, imposes large concentrated forces and moments on the deck at the point where the post is attached to the deck.

- X = distance from the outside edge of the post base plate to the section under investigation, as specified in Figure A13.4.3.1-1 (ft)
 W_b = width of base plate (in.)
 T = tensile force in deck (kip/ft)
 d_b = distance from the outer edge of the base plate to the innermost row of bolts, as shown in Figure A13.4.3.1-1 (in.)
 L = post spacing (ft)
 L_v = longitudinal distribution of vertical force F_v on top of railing (ft)
 F_v = vertical force of vehicle laying on top of rail after impact forces F_i and F_L are over (kips)
 b = length of deck resisting post strength or shear load

Figure A13.4.3.1-1—Effective Length of Cantilever for Carrying Concentrated Post Loads, Transverse or Vertical

A13.4.3.2—Resistance to Punching Shear

For Design Case 1, the factored shear may be taken as:

$$V_u = A_f F_y \quad (\text{A13.4.3.2-1})$$

The factored resistance of deck overhangs to punching shear may be taken as:

$$V_r = \phi V_n \quad (\text{A13.4.3.2-2})$$

$$V_n = v_c \left[W_b + h + 2 \left(E + \frac{B}{2} + \frac{h}{2} \right) \right] h \quad (\text{A13.4.3.2-3})$$

$$v_c = \left(0.0633 + \frac{0.1265}{\beta_c} \right) \sqrt{f'_c} \leq 0.1265 \sqrt{f'_c} \quad (\text{A13.4.3.2-4})$$

Previous editions of the AASHTO *Standard Specifications for Highway Bridges* distributed railing or post loads to the slab using similar simplified analysis, e.g., “The effective length of slab resisting post loadings shall be equal to $E = 0.8x + 3.75$ ft where no parapet is used and equal to $E = 0.8x + 5.0$ ft where a parapet is used, where x is the distance in ft from the center of the post to the point under investigation.”

CA13.4.3.2

Concrete slabs or decks frequently fail in punching shear resulting from the force in the compression flange of the post, C . Adequate thickness, h , edge distance, E , or base plate size (W_b or B or thickness) should be provided to resist this type of failure.

$$\frac{B}{2} + \frac{h}{2} \leq B \quad (\text{A13.4.3.2-5})$$

in which:

$$\beta_c = W_b / d_b \quad (\text{A13.4.3.2-6})$$

where:

- V_u = factored shear force at section (kips)
- A_f = area of post compression flange (in.²)
- F_y = yield strength of post compression flange (ksi)
- V_r = factored shear resistance (kips)
- V_n = nominal shear resistance of the section considered (kips)
- v_c = nominal shear resistance provided by tensile stresses in the concrete (ksi)
- W_b = width of base plate (in.)
- h = depth of slab (in.)
- E = distance from edge of slab to centroid of compressive stress resultant in post (in.)
- B = distance between centroids of tensile and compressive stress resultants in post (in.)
- β_c = ratio of the long side to the short side of the concentrated load or reaction area
- f'_c = 28-day compressive strength of concrete (ksi)
- ϕ = resistance factor = 1.0
- d_b = distance from the outer edge of the base plate to the innermost row of bolts (in.)

The assumed distribution of forces for punching shear shall be as shown in Figure A13.4.3.2-1.

Figure A13.4.3.2-1—Punching Shear Failure Mode

Test results and in-service experience have shown that where deck failures have occurred, the failure mode has been a punching shear-type failure with loss of structural integrity between the concrete and reinforcing steel. Use of various types of shear reinforcement may increase the ultimate strength of the postdeck connection but is ineffective in reducing shear, diagonal tension, or cracking in the deck. Shear resistance can be increased by increasing the slab thickness, base plate width and depth, or edge distance.

SECTION 14

JOINTS AND BEARINGS

Commentary is opposite the text it annotates.

14.1—SCOPE

This Section contains requirements for the design and selection of structural bearings and deck joints.

Units used in this Section shall be taken as kip, in., rad., °F, and Shore Hardness, unless otherwise noted.

14.2—DEFINITIONS

Bearing—A structural device that transmits loads while facilitating translation and/or rotation.

Bearing Joint—A deck joint provided at bearings and other deck supports to facilitate horizontal translation and rotation of abutting structural elements. It may or may not provide for differential vertical translation of these elements.

Bronze Bearing—A bearing in which displacements or rotations take place by the sliding of a bronze surface against a mating surface.

Cotton-Duck-Reinforced Pad (CDP)—A pad made from closely spaced layers of elastomer and cotton duck, bonded together during vulcanization.

Closed Joint—A deck joint designed to prevent the passage of debris through the joint and to safeguard pedestrian and cycle traffic.

Compression Seal—A preformed elastomeric device that is precompressed in the gap of a joint with expected total range of movement less than 2.0 in.

Construction Joint—A temporary joint used to permit sequential construction.

Cycle-Control Joint—A transverse approach slab joint designed to permit longitudinal cycling of integral bridges and attached approach slabs.

Damper—A device that transfers and reduces forces between superstructure elements and/or superstructure and substructure elements, while permitting thermal movements. The device provides damping by dissipating energy under seismic, braking, or other dynamic loads.

Deck Joint—A structural discontinuity between two elements, at least one of which is a deck element. It is designed to permit relative translation and/or rotation of abutting structural elements.

Disc Bearing—A bearing that accommodates rotation by deformation of a single elastomeric disc molded from a urethane compound. It may be movable, guided, unguided, or fixed. Movement is accommodated by sliding of polished stainless steel on polytetrafluorethylene (PTFE).

Double Cylindrical Bearing—A bearing made from two cylindrical bearings placed on top of each other with their axes at right angles to facilitate rotation about any horizontal axis.

Fiberglass-Reinforced Pad (FGP)—A pad made from discrete layers of elastomer and woven fiberglass bonded together during vulcanization.

Fixed Bearing—A bearing that prevents differential longitudinal translation of abutting structural elements. It may or may not provide for differential lateral translation or rotation.

Integral Bridge—A bridge without deck joints.

Joint—A structural discontinuity between two elements. The structural members used to frame or form the discontinuity.

Joint Seal—A poured or preformed elastomeric device designed to prevent moisture and debris from penetrating joints.

Knuckle Bearing—A bearing in which a concave metal surface rocks on a convex metal surface to provide rotation capability about any horizontal axis.

Longitudinal—Parallel with the main span direction of a structure.

Longitudinal Joint—A joint parallel to the span direction of a structure provided to separate a deck or superstructure into two independent structural systems.

Metal Rocker or Roller Bearing—A bearing that carries vertical load by direct contact between two metal surfaces and that accommodates movement by rocking or rolling of one surface with respect to the other.

Modular Bridge Joint System (MBJS)—A sealed joint with two or more elastomeric seals held in place by edgebeams that are anchored to the structural elements (deck, abutment, etc.) and one or more transverse centerbeams that are parallel to the edgebeams. Typically used for movement ranges greater than 4.0 in.

Movable Bearing—A bearing that facilitates differential horizontal translation of abutting structural elements in a longitudinal and/or lateral direction. It may or may not provide for rotation.

Multi-Rotational Bearing—A bearing consisting of a rotational element of the pot type, disc type, or spherical type when used as a fixed bearing and that may, in addition, have sliding surfaces to accommodate translation when used as an expansion bearing. Translation may be constrained to a specified direction by guide bars.

Neutral Point—The point about which all of the cyclic volumetric changes of a structure take place.

Open Joint—A joint designed to permit the passage of water and debris through the joint.

Plain Elastomeric Pad (PEP)—A pad made exclusively of elastomer, which provides limited translation and rotation.

Pot Bearing—A bearing that carries vertical load by compression of an elastomeric disc confined in a steel cylinder and that accommodates rotation by deformation of the disc.

Poured Seal—A seal made from a material that remains flexible (asphaltic, polymeric, or other), which is poured into the gap of a joint and is expected to adhere to the sides of the gap. Typically used only when expected total range of movement is less than 1.5 in.

PTFE—A synthetic polymer resin commonly used for bridge bearing sliding surfaces due to the material's low coefficient of friction.

PTFE Sliding Bearing—A bearing that carries vertical load through contact stresses between a PTFE sheet or woven fabric and its mating surface, and that permits movements by sliding of the PTFE over the mating surface.

Relief Joint—A deck joint, usually transverse, that is designed to minimize either unintended composite action or the effect of differential horizontal movement between a deck and its supporting structural system.

Restrainers—A system of high-strength cables or rods that transfers forces between superstructure elements and/or superstructure and substructure elements under seismic or other dynamic loads after an initial slack is taken up, while permitting thermal movements.

RMS—Root Mean Square.

Rotation about the Longitudinal Axis—Rotation about an axis parallel to the main span direction of the bridge.

Rotation about the Transverse Axis—Rotation about an axis parallel to the transverse axis of the bridge.

Sealed Joint—A joint provided with a joint seal.

Shock Transmission Unit (STU)—A device that provides a temporary rigid link between superstructure elements and/or superstructure and substructure elements under seismic, braking, or other dynamic loads, while permitting thermal movements.

Single Support Bar (SSB) System—An MBJS designed so that only one support bar is connected to all of the centerbeams. The centerbeam/support bar connection typically consists of a yoke through which the support bar slides.

Sliding Bearing—A bearing that accommodates movement by translation of one surface relative to another.

Steel-Reinforced Elastomeric Bearing—A bearing made from alternate laminates of steel and elastomer bonded together during vulcanization. Vertical loads are carried by compression of the elastomer. Movements parallel to the reinforcing layers and rotations are accommodated by deformation of the elastomer.

Strip Seal—A sealed joint with an extruded elastomeric seal retained by edgebeams that are anchored to the structural elements (deck, abutment, etc). Typically used for expected total movement ranges from 1.5 to 4.0 in., although single seals capable of spanning a 5.0 in. gap are also available.

Translation—Horizontal movement of the bridge in the longitudinal or transverse direction.

Transverse—The horizontal direction normal to the longitudinal axis of the bridge.

Waterproofed Joints—Open or closed joints that have been provided with some form of trough below the joint to contain and conduct deck discharge away from the structure.

Welded Multiple-Support-Bar (WMSB) System—An MBJS designed so that each support bar is welded to only one centerbeam. Although some larger WMSB systems have been built and are performing well, WMSB systems are typically impractical for more than nine seals or for movement ranges larger than 27.0 in.

14.3—NOTATION

A	=	plan area of elastomeric element or bearing (in. ²) (14.6.3.1)
A_{Wbot}	=	area of weld at the bottom (in. ²) (14.5.6.9.7b)
A_{Wmid}	=	minimum cross-sectional area of weld (in. ²) (14.5.6.9.7b)
A_{Wtop}	=	area of weld at the top (in. ²) (14.5.6.9.7b)
a_{cr}	=	creep deflection divided by initial dead load deflection (14.7.5.3.6)
B_a	=	dimensionless coefficient used to determine peak hydrostatic stress (14.7.5.3.3)
C_α	=	parameter used to determine hydrostatic stress (14.7.5.3.3)
c	=	minimum vertical clearance between rotating and nonrotating parts (in.); design clearance between piston and pot (in.) (C14.7.3.1) (14.7.4.7)
D	=	diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.); diameter of pad (in.); diameter of the bearing (in.) (14.7.3.2) (14.7.5.1) (14.7.6.3.6) (14.7.5.3.3) (14.7.5.3.4)
D_a	=	dimensionless coefficient used to determine shear strain due to axial load (14.7.5.3.3)
D_d	=	diameter of the disc element (in.) (14.7.8.1) (14.7.8.5)
D_p	=	internal diameter of pot (in.) (14.7.4.3) (14.7.4.6) (14.7.4.7)
D_r	=	dimensionless coefficient used to determine shear strain due to rotation (14.7.5.3.3)
D_1	=	diameter of the rocker or roller surface (in.) (14.7.1.4)
D_2	=	diameter of the mating surface, positive if the curvatures have the same sign, infinite if the mating surface is flat (in.) (14.7.1.4)
d	=	diameter of rocker or roller (in.); the diameter of the hole or holes in the bearing (in.) (C14.7.1.4) (C14.7.5.1)
d_{a1}	=	dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
d_{a2}	=	dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
d_{a3}	=	dimensionless coefficient used to determine shear strain due to axial load (C14.7.5.3.3)
d_{cb}	=	depth of the centerbeam (in.) (14.5.6.9.7b)
d_{sb}	=	depth of the support bar (in.) (14.5.6.9.7b)
E_c	=	effective modulus of elastomeric bearing in compression (ksi); uniaxial compressive stiffness of the cotton-duck bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi) (14.6.3.2) (14.7.6.3.3) (14.7.6.3.5b)
E_s	=	Young's modulus for steel (ksi) (14.7.1.4)

F_y	=	specified minimum yield strength of the weakest steel at the contact surface (ksi); yield strength of steel (ksi); yield strength of steel reinforcement (ksi) (14.7.1.4) (C14.7.1.4) (14.7.4.6) (14.7.4.7) (14.7.5.3.5)
G	=	shear modulus of the elastomer (ksi); shear modulus of the CDP (14.6.3.1) (C14.6.3.1) (C14.6.3.2) (14.7.5.2) (14.7.5.3.3) (14.7.5.3.4) (C14.7.5.3.6) (14.7.6.2) (14.7.6.3.2) (14.7.6.3.4)
H_{bu}	=	lateral load transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.6.3.1)
H_s	=	horizontal load from applicable service load combinations in Table 3.4.1-1 (kip) (14.7.3.3)
H_u	=	lateral load from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.7.4.7)
h_{p1}	=	pot cavity depth (in.) (C14.7.4.3)
h_{p2}	=	vertical clearance between top of piston and top of pot wall (in.) (C14.7.4.3)
h_r	=	depth of elastomeric disc (in.) (14.7.4.3)
h_{ri}	=	thickness of i th elastomeric layer (in.); thickness of i th internal elastomeric layer (in.); layer thickness for FGP which equals the greatest distance between midpoints of two double fiberglass reinforcement layers (in.); thickness of a PEP (in.); mean thickness of two layers of elastomer bonded to the same reinforcement for FGP when the two layers are of different thicknesses (in.) (14.7.5.1) (14.7.5.3.3) (14.7.5.3.5) (14.7.5.3.6) (14.7.6.3.3) (14.7.6.3.7) (14.7.6.3.2)
h_{rt}	=	total elastomer thickness (in.); smaller of total elastomer or bearing thickness (in.) (14.6.3.1) (14.6.3.2) (14.7.5.3.2) (14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.4)
h_s	=	thickness of steel reinforcement (in.) (14.7.5.3.5)
h_w	=	height of the weld (in.); height from top of rim to underside of piston (in.) (14.5.6.9.7b) (C14.7.4.3) (14.7.4.7)
I	=	moment of inertia of plan shape of bearing (in. ⁴) (14.6.3.2)
K	=	rotational stiffness of CDP (kip-in./rad.); bulk modulus (ksi) (C14.6.3.2) (C14.7.5.3.3)
L	=	projected length of the sliding surface perpendicular to the rotation axis (in.); plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.); length of a cotton-duck bearing pad in the plane of rotation (in.) (14.7.3.3) (14.7.5.1) (14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.5b) (14.7.6.3.6)
M_H	=	horizontal bending moment range in the centerbeam on the critical section located at the weld toe due to horizontal force range (kip-in.) (14.5.6.9.7b)
M_{OT}	=	overturning moment range from horizontal reaction force (kip-in.) (14.5.6.9.7b)
M_V	=	vertical bending moment range in the centerbeam on the critical section located at the weld toe due to the vertical force range (kip-in.); component of vertical bending moment range in the support bar due to the vertical reaction force range in the connection located on the critical section at the weld toe (kip-in.) (14.5.6.9.7b)
M_u	=	moment transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip-in.) (14.6.3.2)
m	=	modification factor (14.8.3.1)
n	=	number of interior layers of elastomer (14.7.5.3.3) (14.7.5.4) (14.7.6.1) (14.7.6.3.6)
P_D	=	compressive load at the service limit state (load factor = 1.0) due to permanent loads (kip) (14.7.3.3)
P_S	=	total compressive load from applicable service load combinations in Table 3.4.1-1 (kip) (14.7.1.4) (14.7.3.2)
P_u	=	compressive force from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip) (14.6.3.1)
p	=	allowable bearing at the service limit state (kip/in.) (C14.7.1.4)
R	=	radius of curved sliding surface (in.) (14.6.3.2) (14.7.3.3)
R_H	=	horizontal reaction force range in the connection (kip) (14.5.6.9.7b)
R_o	=	radial distance from center of pot to object in question (e.g., pot wall, anchor bolt, etc.) (in.) (C14.7.4.3)
R_V	=	vertical reaction force range in the connection (kip) (14.5.6.9.7b)
S	=	shape factor of the CDP computed based on Eq. 14.7.5.1-1 and based on total pad thickness; shape factor of an individual elastomer layer; shape factor of PEP (14.6.3.2) (C14.7.5.3.6) (14.7.6.3.2)
S_i	=	shape factor of the i th layer of an elastomeric bearing; shape factor of the i th internal layer of an elastomeric bearing; shape factor for FGP based upon an h_{ri} layer thickness which equals the greatest distance between midpoints of two double fiberglass reinforcement layers (14.7.5.1) (14.7.5.3.3) (14.7.5.3.4) (14.7.5.4) (14.7.6.1) (14.7.6.3.2)
S_{RB}	=	combined bending stress range in the centerbeam (ksi); bending stress range in the support bar due to maximum moment including moment from vertical reaction and overturning at the connection (ksi) (14.5.6.9.7b)
S_{RZ}	=	vertical stress range in the top of the centerbeam-to-support-bar weld from the concurrent reaction of the support beam (ksi); vertical stress range in the bottom of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection (ksi) (14.5.6.9.7b)
S_{Wbot}	=	section modulus of the weld at the bottom for bending in the direction of the support bar axis (in. ³) (14.5.6.9.7b)
S_{Wmid}	=	section modulus of the weld at the most narrow cross-section for bending in the direction normal to the centerbeam axis (in. ³) (14.5.6.9.7b)

S_{Wtop}	=	section modulus of the weld at the top for bending in the direction normal to the centerbeam axis (in. ³) (14.5.6.9.7b)
S_{Xcb}	=	vertical section modulus to the bottom of the centerbeam (in. ³) (14.5.6.9.7b)
S_{Xsb}	=	vertical section modulus of the support bar to the top of the support bar (in. ³) (14.5.6.9.7b)
S_{Ycb}	=	horizontal section modulus of the centerbeam (in. ³) (14.5.6.9.7b)
t_b	=	pot base thickness (in.) (14.7.4.6) (14.7.4.7)
t_p	=	total thickness of CDP (in.) (14.6.3.2) (14.7.6.3.5b)
t_w	=	pot wall thickness (in.) (14.7.4.6) (14.7.4.7)
W	=	roadway surface gap in a transverse deck joint, measured in the direction of travel at the extreme movement determined using the appropriate strength load combination specified in Table 3.4.1-1 (in.); width of the bearing (in.); length of cylinder (in.); length of cylindrical surface (in.); plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.) (14.5.3.2) (14.7.1.4) (14.7.3.2) (14.7.3.3) (14.7.5.1) (C14.7.5.3.3) (14.7.5.3.4) (14.7.6.3.6)
w	=	height of piston rim (in.) (14.7.4.7)
α	=	parameter used to determine hydrostatic stress (1/rad.) (14.7.5.3.3)
γ_a	=	shear strain caused by axial load (14.7.5.3.3)
$\gamma_{a,cy}$	=	shear strain caused by cyclic axial load (14.7.5.3.3)
$\gamma_{a,st}$	=	shear strain caused by static axial load (14.7.5.3.3)
γ_r	=	shear strain caused by rotation (14.7.5.3.3)
$\gamma_{r,cy}$	=	shear strain caused by rotation from cyclic loads (14.7.5.3.3)
$\gamma_{r,st}$	=	shear strain caused by rotation from static loads (14.7.5.3.3)
γ_s	=	shear strain caused by shear displacement (14.7.5.3.3)
$\gamma_{s,cy}$	=	shear strain caused by shear displacement from cyclic loads (14.7.5.3.3)
$\gamma_{s,st}$	=	shear strain caused by shear displacement from static loads (14.7.5.3.3)
β	=	angle between the vertical and resultant applied load (rad.) (14.7.3.3)
ΔF_{TH}	=	constant amplitude fatigue threshold taken from Table 6.6.1.2.3-1 for the detail category of interest (ksi); constant amplitude fatigue threshold for Category A as specified in Article 6.6 (14.5.6.9.7a) (14.7.5.3.5)
Δf	=	force effect, design live load stress range due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5, and calculated as specified in Article 14.5.6.9.7b (ksi) (14.5.6.9.7a) (14.5.6.9.7b)
Δ_O	=	maximum horizontal displacement of the bridge superstructure at the service limit state (in.) (14.7.5.3.2)
Δ_S	=	maximum total shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.); maximum total shear deformation of the bearing from applicable service load combinations in Table 3.4.1-1 (in.); maximum total static or cyclic shear deformation of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.) (14.7.5.3.2) (14.7.6.3.4) (14.7.5.3.3)
Δ_T	=	design thermal movement range computed in accordance with Article 3.12.2 (in.) (14.7.5.3.2)
Δ_u	=	shear deformation from applicable strength and extreme event load combinations in Table 3.4.1-1 (in.) (14.6.3.1)
δ_d	=	initial dead load compressive deflection (in.) (14.7.5.3.6)
δ_L	=	instantaneous live load compressive deflection (in.) (14.7.5.3.6)
δ_{lt}	=	long-term dead load compressive deflection (in.) (14.7.5.3.6)
δ_u	=	vertical deflection from applicable strength load combinations in Table 3.4.1-1 (in.) (C14.7.4.3)
ϵ	=	compressive strain in an elastomer layer (C14.7.5.3.6)
ϵ_a	=	total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi) (14.7.5.3.3) (14.7.5.4)
ϵ_c	=	maximum uniaxial strain due to compression under total load from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.5b)
ϵ_{di}	=	initial dead load compressive strain in i th elastomer layer (14.7.5.3.6)
ϵ_{Li}	=	instantaneous live load compressive strain in i th elastomer layer (14.7.5.3.6)
ϵ_s	=	average compressive strain due to total load from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.3)
ϵ_t	=	maximum uniaxial strain due to combined compression and rotation from applicable service load combinations in Table 3.4.1-1 (14.7.6.3.5b)
θ_L	=	maximum rotation of the CDP at the service limit state (load factor = 1.0) due to live load (rad.) (14.7.6.3.5b)

θ_s	=	maximum service limit state rotation due to total load for bearings unlikely to experience hard contact between metal components (rad.); maximum service limit state design rotation angle specified in Article 14.4.2.1 (rad.); maximum rotation of the CDP from applicable service load combinations in Table 3.4.1-1 (rad.); maximum service limit state design rotation angle about any axis of the pad specified in Article 14.4.2.1 (rad.); maximum static or cyclic service limit state design rotation angle of the elastomer specified in Article 14.4.2.1 (rad.); total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.) (C14.4.2) (14.4.2.1) (14.6.3.2) (14.7.6.3.5b) (14.7.5.3.3) (14.7.5.4)
θ_u	=	maximum strength limit state rotation for bearings that may experience hard contact between metal components (rad.); maximum strength limit state rotation for bearings which are less likely to experience hard contact between metal components (rad.); design rotation from applicable strength load combinations in Table 3.4.1-1 or Article 14.4.2.2.1 (rad.); maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.); maximum strength limit state design rotation angle specified in Article 14.4.2.2.2 (rad.) (C14.4.2) (14.4.2.2.1) (14.4.2.2.2) (C14.7.3.1) (14.7.3.3) (14.7.4.3) (14.7.4.7) (14.7.8.1)
λ	=	compressibility index (C14.7.5.3.3)
μ	=	coefficient of friction; coefficient of friction of the PTFE slider (14.6.3.1) (C14.7.8.4)
σ	=	instantaneous live load compressive stress or dead load compressive stress in an individual elastomer layer (ksi) (C14.7.5.3.6)
σ_{hyd}	=	peak hydrostatic stress (ksi) (14.7.5.3.3)
σ_L	=	average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi) (14.7.5.3.5) (14.7.6.3.2)
σ_s	=	average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi); average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi); average compressive stress due to total static or cyclic load from applicable service load combinations in Table 3.4.1-1 (ksi); total of static and cyclic average compressive stress in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi) (14.7.4.6) (14.7.5.3.4) (14.7.5.3.5) (14.7.6.3.2) (14.7.6.3.3) (14.7.6.3.4) (14.6.3.2) (14.7.6.3.5b) (14.7.5.3.3)
σ_{SS}	=	maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1, or on bronze by Table 14.7.7.3-1 (ksi) (14.7.3.2) (14.7.3.3)
ϕ	=	resistance factor (14.6.1) (14.7.3.2) (C14.7.4.7)
$\phi_{tension}$	=	resistance factor for tension for anchors governed by the steel (14.5.6.9.6)
ϕ_{shear}	=	resistance factor for shear for anchors governed by the steel (14.5.6.9.6)
$\phi_{A\ tension}$	=	resistance factor for tension for anchors governed by the concrete, Condition A, supplemental reinforcement in the failure area (14.5.6.9.6)
$\phi_{A\ shear}$	=	resistance factor for shear for anchors governed by the concrete, Condition A, supplemental reinforcement in the failure area (14.5.6.9.6)
$\phi_{B\ tension}$	=	resistance factor for tension for anchors governed by the concrete, Condition B, no supplemental reinforcement in the failure area (14.5.6.9.6)
$\phi_{B\ shear}$	=	resistance factor for shear for anchors governed by the concrete, Condition B, no supplemental reinforcement in the failure area (14.5.6.9.6)
Ψ	=	subtended semiangle of the curved surface (rad.) (14.7.3.3)

14.4—MOVEMENTS AND LOADS

14.4.1—General

The selection and layout of the joints and bearings shall allow for deformations due to temperature and other time-dependent causes and shall be consistent with the proper functioning of the bridge.

Deck joints and bearings shall be designed to resist loads and accommodate movements at the service and strength limit states and to satisfy the requirements of the fatigue and fracture limit state. The loads induced on the joints, bearings, and structural members depend on the stiffness of the individual elements and the tolerances

C14.4.1

The joints and bearings should allow movements due to temperature changes, creep and shrinkage, elastic shortening due to prestressing, traffic loading, construction tolerances, or other effects. If these movements are restrained, large horizontal forces may result. If the bridge deck is cast-in-place or precast concrete, the bearings at a single support should permit transverse expansion and contraction. Externally applied transverse loads such as wind, earthquake, or traffic braking forces may be carried either on a small number of bearings near the centerline of

considerations often make orientation along rays from a single point impractical.

Prestressing of the deck causes changes in the vertical reactions due to the eccentricity of the forces, which creates restoring forces. Effects of creep and shrinkage also should be considered.

Figure C14.4.1-1 (continued)—Typical Bridge Bearing Schedule

14.4.2—Design Requirements

The minimum thermal movements shall be computed from the extreme temperature specified in Article 3.12.2 and the estimated setting temperatures. Design loads shall be based on the load combinations and load factors specified in Section 3.

C14.4.2

Rotations are considered at the service and strength limit states as appropriate for different types of bearings. Bearings must accommodate movements in addition to supporting loads, so displacements, and in particular rotations, are needed for design. Live load rotations are

typically less than 0.005 rad., but the total rotation due to fabrication and setting tolerances for seats, bearings, and girders may be significantly larger than this. Therefore, the total design rotation is found by summing rotations due to dead and live load and adding allowances for profile grade effects and the tolerances described above. Article 14.8.2 specifies when a tapered plate shall be used if the rotation due to permanent load at the service limit state (load factor = 1.0) becomes excessive. An Owner may reduce the fabrication and setting tolerance allowances if justified by a suitable quality control plan; therefore, these tolerance limits are stated as recommendations rather than absolute limits.

Failure of deformable components such as elastomeric bearings is generally governed by a gradual deterioration under many cycles of load rather than sudden failure under a single load application. Further, the design limits for elastomeric bearings were originally developed under Allowable Strength Design (ASD) service load conditions rather than the strength limit state loads considered during development of the high-load multi-rotational (HLMR) bearing systems. Unless smaller tolerances can be justified, θ_s for elastomeric components is the service limit state rotation plus 0.005 rad.

Metal or concrete components are susceptible to damage under a single rotation that causes metal-to-metal contact, and so they must be designed using the strength limit state rotations. Unless smaller tolerances can be justified, θ_u is the strength limit state rotation plus 0.01 rad.

Disc bearings are less likely to experience metal-to-metal contact than other HLMR bearings because the load element is unconfined. As a result, the total allowance for rotation is consequently smaller for a disc bearing than other HLMR bearings; however, the proof load test, as specified in the *AASHTO LRFD Bridge Construction Specifications*, assures against metal-to-metal contact.

14.4.2.1—Elastomeric Pads and Steel-Reinforced Elastomeric Bearings

The maximum service limit state rotation due to total load, θ_s , for bearings unlikely to experience hard contact between metal components shall be taken as the sum of:

- the rotations from applicable service load combinations in Table 3.4.1-1, and
- an allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

The static and cyclic components of θ_s shall be considered separately when design is according to Article 14.7.5.3.3.

14.4.2.2—High-Load Multi-Rotational (HLMR) Bearings

14.4.2.2.1—Pot Bearings and Curved Sliding Surface Bearings

The maximum strength limit state rotation, θ_u , for bearings such as pot bearings and curved sliding surfaces that may potentially experience hard contact between metal components shall be taken as the sum of:

- the rotations from applicable strength load combinations in Table 3.4.1-1;
- the maximum rotation caused by fabrication and installation tolerances, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value; and
- an allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

14.4.2.2.2—Disc Bearings

The maximum strength limit state rotation, θ_u , for disc bearings which are less likely to experience hard contact between metal components due to their unconfined load element, shall be taken as the sum of:

- the rotations from applicable strength load combinations in Table 3.4.1-1, and
- an allowance for uncertainties, which shall be taken as 0.005 rad. unless an approved quality control plan justifies a smaller value.

14.5—BRIDGE JOINTS

14.5.1—Requirements

14.5.1.1—General

Deck joints shall consist of components arranged to accommodate the translation and rotation of the structure at the joint.

The type of joints and surface gaps shall accommodate the movement of motorcycles, bicycles, and pedestrians, as required, and shall neither significantly impair the riding characteristics of the roadway nor cause damage to vehicles.

The joints shall be detailed to prevent damage to the structure from water, deicing chemicals, and roadway debris.

Longitudinal deck joints shall be provided only where necessary to modify the effects of differential lateral and/or vertical movement between the superstructure and substructure.

C14.5.1.1

To accommodate differential lateral movement, elastomeric bearings or combination bearings with the capacity for lateral movement should be used instead of longitudinal joints where practical.

Joints and joint anchors for grid and timber decks and orthotropic deck superstructures require special details.

14.5.1.2—Structural Design

Joints and their supports shall be designed to withstand force effects for the appropriate design limit state or states over the range of movements for the appropriate design limit state or states, as specified in Section 3. Resistance factors and modifiers shall be taken as specified in Sections 1, 5, 6, 7, and 8, as appropriate.

In snow regions, joint armor, armor connections, and anchors shall be designed to resist force effects that may be imposed on the joints by snagging snowplow blades. The edgebeams and anchorages of strip seals and MBJSes with a skew exceeding 20 degrees in snow regions that do not incorporate protection methods such as those discussed in Article 14.5.3.3 shall be designed for the strength limit state with a minimum snowplow load acting as a horizontal line load on the top surface of the edgebeam in a direction perpendicular to the edgebeam of 0.12 kips/in. for a total length of 10.0 ft anywhere along the edgebeam in either direction. This load includes dynamic load allowance.

The following factors shall be considered in determining force effects and movements:

- properties of materials in the structure, including coefficient of thermal expansion, modulus of elasticity, and Poisson's ratio;
- effects of temperature, creep, and shrinkage;
- sizes of structural components;
- construction tolerances;
- method and sequence of construction;
- skew and curvature;
- resistance of the joints to movements;
- approach pavement growth;
- substructure movements due to embankment construction;
- foundation movements associated with the consolidation and stabilization of subsoils;
- structural restraints; and
- static and dynamic structural responses and their interaction.

C14.5.1.2

The strength limit state for the edgebeams of strip seals and MBJS and anchorage to the concrete or other elements should be checked with this snowplow load if the skew of the joint exceeds 20 degrees relative to a line transverse to the traveling direction. For smaller skews, the blades, which are skewed, will not strike an edgebeam all at once. Protection methods such as those discussed in Article 14.5.3.3 may eliminate the need to design for this snowplow load.

Snowplow blade angles vary regionally. Unless protection methods such as those discussed in Article 14.5.3.3 are used, agencies should avoid MBJS installations with skew that is within three degrees of the plow angle used in that region, to avoid having the plow drop into the gap between centerbeams.

The snowplow load was estimated from snowplow manufacturer information as the force required to deflect a spring-activated blade with 2.0 in. of compression and ten degrees of deflection. The snowplow load includes the effect of impact so the dynamic load allowance should not be applied. The snowplow load should be multiplied by the appropriate strength limit state load factor for live load.

Superstructure movements include those due to placement of bridge decks, volumetric changes, such as shrinkage, temperature, moisture and creep, passage of vehicular and pedestrian traffic, pressure of wind, and the action of earthquakes. Substructure movements include differential settlement of piers and abutments, tilting, flexure, and horizontal translation of wall-type abutments responding to the placement of backfill as well as shifting of stub abutments due to the consolidation of embankments and in-situ soils.

Any horizontal movement of a bridge superstructure will be opposed by the resistance of bridge bearings to movement and the rigidity or flexural resistance of substructure elements. The rolling resistance of rocker and rollers, the shear resistance of elastomeric bearings, or the frictional resistance of bearing sliding surfaces will oppose movement. In addition, the rigidity of abutments and the relative flexibility of piers of various heights and foundation types will affect the magnitude of bearing movement and the bearing forces opposing movement.

Rigid approach pavements composed of cobblestone, brick, or jointed concrete will experience growth or substantial longitudinal pressure due to restrained growth. To protect bridge structures from these potentially destructive pressures and to preserve the movement range of deck joints and the performance of joint seals, either effective pavement pressure relief joints or pavement anchors should be provided in approach pavements, as described in *Transportation Research Record 1113*.

The length of superstructure affecting the movement at one of its joints shall be the length from the joint being considered to the structure's neutral point.

For a curved superstructure that is laterally unrestrained by guided bearings, the direction of longitudinal movement at a bearing joint may be assumed to be parallel to the chord of the deck centerline taken from the joint to the neutral point of the structure.

The potential for unaligned longitudinal and rotational movement of the superstructure at a joint should be considered in designing the vertical joints in curbs and raised barriers and in determining the appropriate position and orientation of closure or bridging plates.

14.5.1.3—Geometry

The moving surfaces of the joint shall be designed to work in concert with the bearings to avoid binding the joints and adversely affecting force effects imposed on bearings.

14.5.1.4—Materials

The materials shall be selected so as to ensure that they are elastically, thermally, and chemically compatible. Where substantial differences exist, material interfaces shall be formulated to provide fully functional systems.

Materials, other than elastomers, should have a service life of not less than 75 years. Elastomers for joint seals and troughs should provide a service life not less than 25 years.

Joints exposed to traffic should have a skid-resistant surface treatment, and all parts shall be resistant to attrition and vehicular impact.

Except for high-strength bolts, fasteners for joints exposed to deicing chemicals shall be made of stainless steel.

14.5.1.5—Maintenance

Deck joints shall be designed to operate with a minimum of maintenance for the design life of the bridge.

Detailing should permit access to the joints from below the deck and provide sufficient area for maintenance.

Mechanical and elastomeric components of the joint shall be replaceable.

Joints shall be designed to facilitate vertical extension to accommodate roadway overlays.

When horizontal movement at the ends of a superstructure is due to volumetric changes, the forces generated within the structure in resistance to these changes are balanced. The neutral point can be located by estimating these forces, taking into account the relative resistance of bearings and substructures to movement. The length of superstructure contributing to movement at a particular joint can then be determined.

C14.5.1.3

For square or slightly skewed bridge layouts, moderate roadway grades at the joint and minimum changes in both horizontal and vertical joint alignment may be preferred in order to simplify the movements of joints and to enhance the performance of the structure.

C14.5.1.4

Preference should be given to those materials that are least sensitive to field compounding and installation variables and to those that can be repaired and altered by nonspecialized maintenance forces. Preference should also be given to those components and devices that will likely be available when replacements are needed.

C14.5.1.5

The position of bearings, structural components, joints, and abutment backwalls, and the configuration of pier tops should be chosen so as to provide sufficient space and convenient access to joints from below the deck. Inspection hatches, ladders, platforms, and/or catwalks shall be provided for the deck joints of large bridges not directly accessible from the ground.

14.5.2—Selection

14.5.2.1—Number of Joints

The number of movable deck joints in a structure should be minimized. Preference shall be given to continuous deck systems and superstructures and, where appropriate, integral bridges.

The need for a fully functional cycle-control joint shall be investigated on approaches of integral bridges.

Movable joints may be provided at abutments of single-span structures exposed to appreciable differential settlement. Intermediate deck joints should be considered for multiple-span bridges where differential settlement would result in significant overstresses.

14.5.2.2—Location of Joints

Deck joints should be avoided over roadways, railroads, sidewalks, other public areas, and at the low point of sag vertical curves.

Deck joints should be positioned with respect to abutment backwalls and wingwalls to prevent the discharge of deck drainage that accumulates in the joint recesses onto bridge seats.

Open deck joints should be located only where drainage can be directed to bypass the bearings and discharged directly below the joint.

Closed or waterproof deck joints should be provided where joints are located directly above structural members and bearings that would be adversely affected by debris accumulation. Where deicing chemicals are used on bridge decks, sealed or waterproofed joints should be provided.

For straight bridges, the longitudinal elements of deck joints, such as plate fingers, curb and barrier plates, and MBJS support bars, should be placed parallel to the longitudinal axis of the deck. For curved and skewed structures, allowance shall be made for deck end movements consistent with that provided by the bearings.

Where possible, MBJSes should not be located in the middle of curved bridges to avoid unforeseeable movement demands. Preferably, MBJSes should not be located near traffic signals or toll areas so as to avoid extreme braking forces.

C14.5.2.1

Integral bridges, bridges without movable deck joints, should be considered where the length of superstructure and flexibility of substructures are such that secondary stresses due to restrained movement are controlled within tolerable limits.

Where a floorbeam design that can tolerate differential longitudinal movements resulting from relative temperature and live load response of the deck and independent supporting members, such as girders and trusses, is not practical, relief joints in the deck slab, movable joints in the stringers, and movable bearings between the stringers and floorbeams should be used.

Long-span deck-type structures with steel stringers that are slightly skewed, continuous, and composite can withstand substantial differential settlement without significant secondary stresses. Consequently, intermediate deck joints are rarely necessary for multiple-span bridges supported by secure foundations, i.e., piles, bedrock, dense subsoils, etc. Because the stresses induced by settlement can alter the point of inflection, a more conservative control of fatigue-prone detail locations is appropriate.

Guidance on the movements of the substructure can be found in Articles 10.5.2, 10.6.2, 10.7.2, and 10.8.2.

C14.5.2.2

Open joints with drainage troughs should not be placed where the use of horizontal drainage conductors would be necessary.

End rotations of deck-type structures occur about axes that are roughly parallel to the centerline of bearings along the bridge seat. In skewed structures, these axes are not normal to the direction of longitudinal movement. Sufficient lateral clearances between plates, open joints, or elastomeric joint devices should be provided to prevent binding due to lack of alignment between longitudinal and rotational movements.

14.5.3—Design Requirements

14.5.3.1—Movements during Construction

Where practicable, construction staging should be used to delay construction of abutments and piers located in or adjacent to embankments until the embankments have been placed and consolidated. Otherwise, deck joints should be sized to accommodate the probable abutment and pier movements resulting from embankment consolidation after their construction.

Closure pours in concrete structures may be used to minimize the effect of prestress-induced shortening on the width of seals and the size of bearings.

C14.5.3.1

Where it is either desirable or necessary to accommodate settlement or other construction movements prior to deck joint installation and adjustment, the following construction controls may be used:

- placing abutment embankment prior to pier and abutment excavation and construction,
- surcharging embankments to accelerate consolidation and adjustment of in-situ soils,
- backfilling wall-type abutments up to subgrade prior to placing bearings and backwalls above bridge seats, and
- using deck slab blockouts to allow placing the major portion of span dead loads prior to joint installation.

14.5.3.2—Design Movements

A roadway surface gap, W (in.), in a transverse deck joint, measured in the direction of travel at the maximum movement determined using the appropriate strength load combination specified in Table 3.4.1-1 shall satisfy:

- For a single gap:

$$W \leq 4.0 \text{ in.} \quad (14.5.3.2-1)$$

- For multiple modular gaps:

$$W \leq 3.0 \text{ in.} \quad (14.5.3.2-2)$$

For steel and nonprestressed wood superstructures, the minimum opening of a transverse deck joint and roadway surface gap therein shall not be less than 1.0 in. for movements determined using the appropriate strength load combination specified in Table 3.4.1-1. For concrete superstructures, consideration shall be given to the opening of joints due to creep and shrinkage that may require initial minimum openings of less than 1.0 in. at the strength limit state.

Unless more appropriate criteria are available, the maximum surface gap of longitudinal roadway joints shall not exceed 1.0 in. at the strength limit state.

At the maximum movement determined using the appropriate strength load combination specified in Table 3.4.1-1, the opening between adjacent fingers on a finger plate shall not exceed:

- 2.0 in. for longitudinal openings greater than 8.0 in., or
- 3.0 in. for longitudinal openings 8.0 in. or less.

C14.5.3.2

Safe operation of motorcycles is one of the prime considerations in choosing the size of openings for finger plate joints.

The finger overlap at the maximum movement shall be not less than 1.5 in. at the strength limit state.

Where bicycles are anticipated in the roadway, the use of special covering floor plates in shoulder areas shall be considered.

14.5.3.3—Protection

Deck joints shall be designed to accommodate the effects of vehicular traffic, pavement maintenance equipment, and other long-term environmentally induced damage.

Joints in concrete decks should be armored with steel shapes, weldments, or castings. Such armor shall be recessed below roadway surfaces and be protected from snowplows.

Jointed approach pavements shall be provided with pressure relief joints and/or pavement anchors. Approaches to integral bridges shall be provided with cycle-control pavement joints.

14.5.3.4—Bridging Plates

Joint bridging plates and finger plates should be designed as cantilever members capable of supporting wheel loads at the strength limit state.

The differential settlement between the two sides of a joint bridging plate shall be investigated. If the differential settlement cannot be either reduced to acceptable levels or accommodated in the design and detailing of the bridging plates and their supports, a more suitable joint should be used.

Rigid bridging plates shall not be used at elastomeric bearings or hangers unless they are designed as cantilever members, and the contract documents require them to be installed to prevent binding of the joints due to horizontal and vertical movement at bearings.

14.5.3.5—Armor

Joint-edge armor embedded in concrete substrates should be pierced by 0.75-in. minimum-diameter vertical vent holes spaced on not more than 18.0-in. centers.

C14.5.3.3

Snowplow protection for deck joint armor and joint seals may consist of any one of the following options:

- concrete buffer strips 12.0 to 18.0 in. wide with joint armor recessed 0.25 to 0.375 in. below the surface of such strips,
- tapered steel ribs protruding up to 0.50 in. above roadway surfaces to lift the plow blades as they pass over the joints,
- recesses in flexible pavement to position armor below anticipated rutting, but not so deep as to pond water.

Additional precautions to prevent damage by snowplows should be considered where the skew of the joints coincides with the skew of the plow blades, typically 30 degrees to 35 degrees.

C14.5.3.4

Where binding of bridging plates can occur at bearing joints due to differential vertical translation of abutting structural elements or due to the longitudinal movement of bridging plates and bearings on different planes, the plates can be subjected to the total dead and live load superstructure reaction. Where bridging plates are not capable of resisting such loads, they may fail and become a hazard to the movement of vehicular traffic.

Thick elastomeric bearings responding to the application of vertical load or short hangers responding to longitudinal deck movements may cause appreciable differential vertical translation of abutting structural elements at bearing joints. To accommodate such movements, an appropriate type of sealed joint or a waterproofed open joint, rather than a structural joint with rigid bridging plates or fingers, should be provided.

C14.5.3.5

Vent holes are necessary to help expel entrapped air and facilitate the attainment of a solid concrete substrate under joint-edge armor.

Metal surfaces wider than 12.0 in. that are exposed to vehicular traffic shall be provided with an antiskid treatment.

14.5.3.6—Anchors

Armor anchors or shear connectors should be provided to ensure composite behavior between the concrete substrate and the joint hardware and to prevent subsurface corrosion by sealing the boundaries between the armor and concrete substrate. Anchors for edgebeams of strip seals and MBJSes shall be designed for the snowplow load as required in Article 14.5.1.2.

Anchors for roadway joint armor shall be directly connected to structural supports or extended to effectively engage the reinforced concrete substrate. The free edges of roadway armor, more than 3.0 in. from other anchors or attachments, shall be provided with 0.50-in. diameter end-welded studs not less than 4.0 in. long spaced at not more than 12.0 in. from other anchors or attachments. The edges of sidewalk and barrier armor shall be similarly anchored.

14.5.3.7—Bolts

Anchor bolts for bridging plates, joint seals, and joint anchors shall be fully torqued high-strength bolts. The interbedding of nonmetallic substrates in connections with high-strength bolts shall be avoided. Cast-in-place anchors shall be used in new concrete. Expansion anchors, countersunk anchor bolts, and grouted anchors shall not be used in new construction.

14.5.4—Fabrication

Shapes or plates shall be of sufficient thickness to stiffen the assembly and minimize distortion due to welding.

To ensure appropriate fit and function, the contract documents should require that:

- joint components be fully assembled in the shop for inspection and approval,
- joints and seals be shipped to the jobsite fully assembled, and
- assembled joints in lengths up to 60.0 ft be furnished without intermediate field splices.

14.5.5—Installation

14.5.5.1—Adjustment

The setting temperature of the bridge or any component thereof shall be taken as the actual air temperature averaged over the 24-hour period immediately preceding the setting event.

The contract documents should require hand packing of concrete under joint armor.

C14.5.3.6

Snow plow impact should also be considered in designing anchors.

C14.5.3.7

Grouted anchors may be used for maintenance of existing joints.

C14.5.4

Joint straightness and fit of components should be enhanced by the use of shapes, bars, and plates 0.50 in. or thicker.

Construction procedures and practices should be developed to allow joint adjustment for installation temperatures without altering the orientation of joint parts established during shop assembly.

C14.5.5.1

Except for short bridges where installation temperature variations would have only a negligible effect on joint width, plans for each expansion joint should include required joint installation widths for a range of

For long structures, an allowance shall be included in the specified joint widths to account for the inaccuracies inherent in establishing installation temperatures and for superstructure movements that may take place during the time between the setting of the joint width and completion of joint installation. In the design of joints for long structures, preference should be given to those devices, details, and procedures that will allow joint adjustment and completion in the shortest possible time.

Connections of joint supports to primary members should allow horizontal, vertical, and rotational adjustments.

Construction joints and blockouts should be used where practicable to permit the placement of backfill and the major structure components prior to joint placement and adjustment.

14.5.5.2—Temporary Supports

Deck joints shall be furnished with temporary devices to support joint components in proper position until permanent connections are made or until encasing concrete has achieved an initial set. Such supports shall provide for adjustment of joint widths for variations in installation temperatures.

14.5.5.3—Field Splices

Joint designs shall include details for transverse field splices for staged construction and for joints longer than 60.0 ft. Where practicable, splices should be located outside of wheel paths and gutter areas.

Details in splices should be selected to maximize fatigue life.

Field splices provided for staged construction shall be located with respect to other construction joints to provide sufficient room to make splice connections.

When a field splice is required, the contract documents should require that permanent seals not be placed until after joint installation has been completed. Where practicable, only those seals that can be installed in one continuous piece should be used. Where field splicing is unavoidable, splices should be vulcanized.

14.5.6—Considerations for Specific Joint Types

14.5.6.1—Open Joints

Open deck joints shall permit the free flow of water through the joint. Open deck joints should not be used

probable installation temperatures. For concrete structures, use of a concrete thermometer and measurement of temperature in expansion joints between superstructure units may be considered.

An offset chart for installation of the expansion joints is recommended to account for uncertainty in the setting temperature at the time of design. The designer may provide offset charts in appropriate increments and include the chart on the design drawings. Placement of the expansion joint hardware during deck forming should accommodate differences between setting temperature and an assumed design installation temperature.

Construction procedures that will allow major structure dead load movements to occur prior to placement and adjustment of deck joints should be used.

C14.5.5.2

Temporary attachments should be released to avoid damaging anchorage encasements due to movement of superstructures responding to rapid temperature changes.

For long structures with steel primary members, instructions should be included in the contract documents to ensure the removal of temporary supports or release of their connections as soon as possible after concrete placement.

C14.5.5.3

Splices for less critical portions of joints or for lightly loaded joints should be provided with connections rigid enough to withstand displacement if joint armor is used as a form during concrete placement.

C14.5.6.1

Under certain conditions, open deck joints can provide an effective and economical solution. In general, open

where deicing chemicals are applied. Piers and abutments at open joints shall satisfy the requirements of Article 2.5.2 in order to prevent the accumulation of water and debris.

joints are well-suited for secondary highways where little sand and salt are applied during the winter. They are not suited for urban areas where the costs of provisions for deck joint drainage are high.

Satisfactory performance depends upon an effective deck drainage system, control of deck discharge through joints, and containment and disposal of runoff from the site. It is essential that surface drainage and roadway debris not be permitted to accumulate on any part of the structure below such joints.

Protection against the deleterious effects of deck drainage may include shaping structural surfaces to prevent the retention of roadway debris and providing surfaces with deflectors, shields, covers, and coatings.

14.5.6.2—Closed Joints

Sealed deck joints shall seal the surface of the deck, including curbs, sidewalks, medians, and, where necessary, parapet and barrier walls. The sealed deck joint shall prevent the accumulation of water and debris, which may restrict its operation. Closed or waterproof joints exposed to roadway drainage shall have structure surfaces below the joint shaped and protected as required for open joints.

Joint seals should be watertight and extrude debris when closing.

Drainage accumulated in joint recesses and seal depressions shall not be discharged on bridge seats or other horizontal portions of the structure.

Where joint movement is accommodated by a change in the geometry of elastomeric glands or membranes, the glands or membranes shall not come into direct contact with the wheels of vehicles.

C14.5.6.2

Completely effective joint seals have yet to be developed for some situations, particularly where there are severely skewed joints with raised curbs or barriers, and especially where joints are subjected to substantial movements. Consequently, some type of open or closed joint, protected as appropriate, should be considered instead of a sealed joint.

Sheet and strip seals that are depressed below the roadway surface and that are shaped like gutters will fill with debris. They may burst upon closing, unless the joints that they seal are extended straight to the deck edges where accumulated water and debris can be discharged clear of the structure. To allow this extension and safe discharge, it may be necessary to move the backwalls and bridge seats of some abutment types forward until the backwalls are flush with the wingwalls, or to reposition the wingwalls so that they do not obstruct the ends of the deck joints.

14.5.6.3—Waterproofed Joints

Waterproofing systems for joints, including joint troughs, collectors, and downspouts, shall be designed to collect, conduct, and discharge deck drainage away from the structure.

In the design of drainage troughs, consideration should be given to:

- trough slopes of not less than 1.0 in./ft;
- open-ended troughs or troughs with large discharge openings;
- prefabricated troughs;
- troughs composed of reinforced elastomers, stainless steel, or other metal with durable coatings;
- stainless steel fasteners;
- troughs that are replaceable from below the joint;

Closed cell seals shall not be used in joints where they would be subjected to sustained compression, unless seal and adhesive adequacy have been documented by long-term demonstration tests for similar applications.

14.5.6.7—Sheet and Strip Seals

In the selection and application of either sheet or strip seals, consideration should be given to:

- joint designs for which glands with anchorages are not exposed to vehicular loadings;
- joint designs that allow complete closure without detrimental effects to the glands;
- joint designs where the elastomeric glands extend straight to the deck edges rather than being bent up at curbs or barriers;
- decks with sufficient crown or superelevation to ensure lateral drainage of accumulated water and debris;
- glands that are shaped to expel debris; and
- glands without abrupt changes in either horizontal or vertical alignment.

Sheet and strip seals should be spliced only when specifically approved by the Engineer.

14.5.6.8—Plank Seals

Application of plank seals should be limited to structures on secondary roads with light truck traffic, and that have unskewed or slightly skewed joints.

Consideration should be given to:

- seals that are provided in one continuous piece for the length of the joint;
- seals with splices that are vulcanized; and
- anchorages that can withstand the forces necessary to stretch or compress the seal.

14.5.6.9—Modular Bridge Joint Systems (MBJSes)

14.5.6.9.1—General

These Articles address the performance requirements, strength limit state design, and fatigue limit state design of MBJSes.

These Specifications were developed primarily for, and shall be applied to, the two common types of MBJS, which are multiple-support-bar and SSB systems, including swivel-joint systems.

C14.5.6.8

Plank-type seals should not be used in joints with unpredictable movement ranges.

C14.5.6.9.1

These MBJS design specifications provide a rational and conservative method for the design of the main load-carrying steel components of MBJSes. These Specifications do not specifically address the functional design of MBJSes or the design of the elastomeric parts. These Specifications are based on research described in Dexter et al. (1997), which contains extensive discussion of the loads and measured dynamic response of MBJSes and the fatigue resistance of common MBJS details. Fatigue test procedures were developed for the structural details as well.

Common types of MBJSes are shown in Figures C14.5.6.9.1-1 through C14.5.6.9.1-3.

Figure C14.5.6.9.1-1—Cut-away View of Typical WMSB MBJS Showing Support Bars Sliding within Support Boxes

Figure C14.5.6.9.1-2—Cross-Section View of Typical SSB MBJS Showing Multiple Centerbeams with Yokes Sliding on a Single Support Bar

Figure C14.5.6.9.1-3—Cut-away View of a "Swivel Joint," i.e., a Special Type of SSB MBJS with a Swiveling Single Support Bar

14.5.6.9.2—Performance Requirements

The required minimum MBJS movement range capabilities for the six possible degrees of freedom given in Table 14.5.6.9.2-1 shall be added to the maximum movement and rotations calculated for the entire range of seals in the MBJS determined using the appropriate strength load combination specified in Table 3.4.1-1.

Table 14.5.6.9.2-1—Additional Minimum Movement Range Capability for MBJSes

Type of Movement	Minimum Design Movement Range*
Longitudinal Displacement	Estimated Movement + 1.0 in.
Transverse Movement	1.0 in.
Vertical Movement	1.0 in.
Rotation around Longitudinal Axis	1°
Rotation Around Transverse Axis	1°
Rotation Around Vertical Axis	0.5°

* Total movement ranges presented in the table are twice the plus or minus movement.

C14.5.6.9.2

The MBJS should be designed and detailed to minimize excessive noise or vibration during the passage of traffic.

A common problem with MBJSes is that the seals fill with debris. Traffic passing over the joint can work the seal from its anchorage by compacting this debris. MBJS systems can eject most of this debris in the traffic lanes if the seals are opened to near their maximum opening. Therefore, it is prudent to provide for additional movement capacity.

MBJSes should permit movements in all six degrees of freedom, i.e., translations in all three directions and rotations about all three axes. While it is mandatory to provide at least 1.0 in. movement in the longitudinal direction, as shown in Table 14.5.6.9.2-1, no more than 2.0 in. should be provided in addition to the maximum calculated movement if feasible. Also, more than 1.0 in. should not be added if it causes a further seal to be used. In the five degrees of freedom other than the longitudinal direction, the MBJS should provide the maximum calculated movement in conjunction with providing for at least the minimum additional movement ranges shown in Table 14.5.6.9.2-1. Half of the movement range shall be assumed to occur in each direction about the mean position. Some bridges may require greater than the additional specified minimum values.

The designer should consider showing the total estimated transverse and vertical movement in each direction, as well as the rotation in each direction about the three principal axes on the contract plans. Vertical movement due to vertical grade, with horizontal bearings, and vertical movement due to girder and rotation may also be considered.

Further design guidelines and recommendations can be found in Chapter 19 of the *AASHTO LRFD Bridge Construction Specifications* and Dexter et al. (1997).

14.5.6.9.3—Testing and Calculation Requirements

MBJSes shall satisfy all test specifications detailed in Appendix A19 of the *AASHTO LRFD Bridge Construction Specifications*.

Each configuration of MBJS shall be designed for the strength and fatigue, and fracture limit states as specified in Articles 14.5.6.9.6 and 14.5.6.9.7.

14.5.6.9.4—Loads and Load Factors

Edgebeams, anchors, centerbeams, support bars, connections between centerbeams and support bars, support boxes, and connections, if any, to elements of the structure, such as girders, truss chords, crossbeams, etc., and other structural components shall be designed for the strength and fatigue and fracture limit states for the simultaneous application of vertical and horizontal axle loads. The edgebeams and anchors of MBJSes in snow

C14.5.6.9.4

The vertical axle load for fatigue limit state design is one-half the 32.0-kip axle load of the design truck specified in Article 3.6.1.2.2 or 16.0 kips. This reduction recognizes that the main axles of the design truck are a simplification of actual tandem axles. The simplification is not satisfactory for MBJS and other expansion joints because expansion joints experience a separate stress cycle for each individual axle.

regions shall also be designed for the strength limit state for the snowplow load defined in Article 14.5.1.2. The design lane load need not be considered for MBJS.

The two wheel loads from each axle shall be centered 72.0 in. apart transversely. Each wheel load shall be distributed to the various edgebeams and centerbeams as specified in Article 14.5.6.9.5. The fraction of the wheel loads applied to each member shall be line loads applied at the center of the top surface of a member with a width of 20.0 in.

For the strength limit state, the vertical wheel loads shall be from the design tandem specified in Article 3.6.1.2.3; the wheel loads from the design truck in Article 3.6.1.2.2 need not be considered for the strength limit state of MBJSes. Both of the tandem axles shall be considered in the design if the joint opening exceeds 4.0 ft. The vertical wheel load shall be increased by the dynamic load allowance specified for deck joints in Table 3.6.2.1-1.

The horizontal load for the strength limit state shall be 20 percent of the vertical wheel load ($LL + IM$), applied along the same line at the top surface of the centerbeam or edgebeam. For MBJSes installed on vertical grades in excess of five percent, the additional horizontal component due to grade shall be added to the horizontal wheel load.

To investigate the strength limit state, the axles shall be oriented and positioned transversely to maximize the force effect under consideration.

The vertical wheel load ranges for the fatigue limit state shall be from the largest axle load from the three-axle design truck specified in Article 3.6.1.2.2. For fatigue limit state design of MBJSes, this axle load shall be considered as the total load on a tandem, i.e., the total load shall be split into two axle loads spaced 4.0 ft apart. Both of these tandem axles shall be considered in the design if the joint opening exceeds 4.0 ft. The vertical load range shall be increased by the dynamic load allowance specified for deck joints in Table 3.6.2.1-1. The load factors to consider shall be as specified in Table 3.4.1-1 for the Fatigue I case.

The horizontal load ranges for the fatigue limit state shall be at least 20 percent of the vertical wheel load range ($LL + IM$) for fatigue. For MBJS installed on vertical grades in excess of five percent, the additional horizontal component due to grade shall be added to the horizontal wheel load range.

To investigate the fatigue limit state, the axles shall be oriented perpendicular to the travel direction only, but shall be positioned transversely to maximize the force effect under consideration. In bridges with a skew greater than 14 degrees, the two wheel loads from an axle may not be positioned on a centerbeam simultaneously, and the maximum stress ranges at a critical detail on the centerbeam may be the difference between the stresses due to the application of each wheel load separately.

For strength limit state design, there are two load combinations that could be considered. However, recognizing that each main axle of the design truck should actually be treated as 32.0-kip tandems, it is clear the 50.0-kip design tandem, which is not used for fatigue limit state design, will govern for strength limit state design.

The loads specified for fatigue limit state design actually represent load ranges. When these loads are applied to a structural analysis model with no dead load applied to the model, the moment, force, or stress that is computed everywhere represents a moment, force, or stress range. In service, these stress ranges are partly due to the downward load and partly due to upward rebound from the dynamic impact effect.

The dynamic load allowance (impact factor) specified for deck joints of 75 percent was developed from field testing of MBJSes conducted in Europe and was confirmed in field tests described in Dexter et al. (1997). The stress range due to the load plus this dynamic load allowance represents the sum of the downward part of that stress range and the upward part of the stress range due to rebound. Measurements, described in Dexter et al. (1997), showed that the maximum downward amplification of the static load is 32 percent, with about 31 percent rebound in the upward direction.

The vertical axle load range with impact for fatigue limit state design is one-half of the largest axle load of the design truck specified in Article 3.6.1.2.2, multiplied by 1.75 to include the dynamic load allowance, multiplied by a load factor of 1.5 (or 2.0×0.75), as specified in Table 3.4.1-1 for the Fatigue I case, or 42.0 kips. The 0.75 load factor transforms axles of an HS20 truck to those of an HS15 fatigue truck, which is presumed to represent the effective stress range. The factor 2.0 amplifies the effective stress range for the fatigue limit state to the presumed maximum expected stress range which with impact is required to be less than the fatigue threshold in Article 14.5.6.9.7a. It is the intent of the fatigue design specifications that the static load without impact considered (24.0 kips or 42.0 kips/1.75) should be infrequently exceeded, see Dexter et al. (1997).

Field measurements were taken at a variety of locations; so typical truck excitations should be reflected in the dynamic load allowance. However, a joint located on a structure with significant settlement or deterioration of the approach roadway may be exposed to a dynamic load allowance 20 percent greater due to dynamic excitation of the trucks.

MBJSes with centerbeam spans less than 4.0 ft are reported to have lower dynamic effects (Pattis, 1993; Tschemmerneegg and Pattis, 1994). The fatigue limit state

design provisions of Article 14.5.6.9.7 happen to also limit the spans of typical 5.0-in.-deep centerbeams to around 4.0 ft anyway, so there is no need for a specific limitation of the span.

At sites with a tight horizontal curve (less than 490-ft radius) the vertical moments could be about 20 percent higher than would be expected. An increase in the dynamic load allowance for cases where there is a tight horizontal curve is not considered necessary if the speed of trucks on these curves is limited. In this case, the dynamic impact will be less than for trucks at full speed and the decreased dynamic impact will approximately offset the increased vertical load due to the horizontal curve.

The dynamic load allowance is very conservative when applied to the vertical load for strength limit state design, since in strength limit state design peak loads, not load ranges, are of interest. In the measurements made on MBJSes in the field, the maximum downward vertical moment was only 1.32 times the static moment. There are usually no consequences of this conservative simplification since the proportions of the members are typically governed by fatigue and not strength.

The horizontal loads are taken as 20 percent of the vertical load plus the dynamic load allowance. In-service measurements, described in Dexter et al. (1997), indicate that the 20 percent horizontal load range is the largest expected from traffic at steady speeds, including the effect of acceleration and routine braking. The 20 percent horizontal load range for fatigue limit state design represents ten percent forward and ten percent backward.

Where strength limit state design is considered, the 20 percent horizontal load requirement corresponds to a peak load of 20 percent applied in one direction. The 20 percent horizontal peak load is appropriate for strength limit state design. However, the field measurements, described in Dexter et al. (1997), show that the horizontal force effects resulting from extreme braking can be much greater than at steady speeds. Therefore, the 20 percent peak horizontal load represents the extreme braking for strength limit state design. For fatigue limit state design, these extreme events occur so infrequently that they do not usually need to be taken into account in most cases.

Special consideration should be given to the horizontal forces if the MBJS is located near a traffic light, stop sign, or toll facility, or if the centerbeam is unusually wide.

14.5.6.9.5—Distribution of Wheel Loads

Each edgebeam shall be designed for 50 percent of the vertical and horizontal wheel loads specified in Article 14.5.6.9.4.

Table 14.5.6.9.5-1 specifies the centerbeam distribution factor, i.e., the percentage of the design vertical and horizontal wheel loads specified in Article 14.5.6.9.4 that shall be applied to an individual centerbeam for the design of that centerbeam and associated support bars. Distribution factors shall be interpolated for centerbeam top flange widths not given in

C14.5.6.9.5

For the convenience of the designer, the vertical axle load range with impact for fatigue limit state design on one centerbeam 2.5 in. or less in width is 21.0 kips. On the centerbeam, each fraction of the wheel load of 10.5 kips is spaced 72.0 in. apart distributed over a width of 20.0 in. with a magnitude of 0.525 kips/in.

The distribution factor, i.e., the fraction of the design wheel load range assigned to a single centerbeam, is a function of applied load, tire pressure, gap width, and centerbeam height mismatch. Unfortunately, many of the

the table, but in no case shall the distribution factor be taken as less than 50 percent. The remainder of the load shall be divided equally and applied to the two adjacent centerbeams or edgebeams.

Table—14.5.6.9.5-1 Centerbeam Distribution Factors

Width of Centerbeam Top Flange	Distribution Factor
2.5 in. (or less)	50%
3.0 in.	60%
4.0 in.	70%
4.75 in.	80%

factors affecting the distribution factor are difficult to quantify individually and even more difficult to incorporate in an equation or graph. Existing methods to estimate the distribution factor do not incorporate all of these variables and consequently can be susceptible to error when used outside the originally intended range. In view of this uncertainty, a simplified tabular method is used to estimate the distribution factor. Alternative methods are permitted if they are based on documented test data.

Wheel load distribution factors shown in Table 14.5.6.9.5-1 are based on field and laboratory testing, described in Dexter et al. (1997), and were found to be in acceptable agreement with the findings of other researchers. These distribution factors are based on the worst-case assumption of maximum joint opening (maximum gap width). Calculating the stress ranges at maximum gap opening is approximately 21 percent too conservative for fatigue limit state design. However, as explained in Dexter et al. (1997), this conservatism compensates for a lack of conservatism in the AASHTO fatigue design truck axle load.

For comparison to the fatigue threshold, the factored static axle load range, without the dynamic load allowance, would be 24.0 kips (or 42.0 kips/1.75, as discussed in Article C14.5.6.9.4). The static axle load range at the fatigue limit state is supposed to represent an axle load that is rarely exceeded. However, the fatigue limit state design load is multiplied by a distribution factor that is 21 percent too large, so in effect, this is equivalent to a static axle load range at the fatigue limit state of 29.0 kips that should be rarely exceeded, if correct distribution factors were used. This is more consistent with the statistics of weigh-in-motion data where axle loads with exceedance levels of 0.01 percent were up to 36.0 kips, see Schilling (1990) or Nowak and Laman (1995).

A mitigating factor on the impact of these larger axle loads is that the distribution factor decreases with increasing axle load. Because of this effect, measurements reported in Dexter et al. (1997) show that as the axle load is increased from 24.0 to 36.0 kips, an increase of 50 percent, the load on one centerbeam increases from 12.6 to only 14.6 kips, an increase of only 16 percent.

Even though maximum gap opening occurs only rarely, it is an appropriate assumption for checking the Strength I limit state. No additional conservatism is warranted in this case, however, because the dynamic load allowance is about 32 percent too conservative for strength limit state design only, as discussed in Article C14.5.6.9.

Another advantage of using the conservative distribution factors is that it may compensate for ignoring the effect of potential centerbeam height mismatch. Laboratory studies show that a height mismatch of 0.125 in. resulted in a 24 percent increase in the measured distribution factor, see Dexter et al. (1997). Although such mismatch is not common presently, and recent

construction specifications are supposed to preclude this mismatch, it is prudent to anticipate that it may occur.

14.5.6.9.6—Strength Limit State Design Requirements

Where the MBJS is analyzed for the strength limit state, the gap between centerbeams shall be assumed to be at the fully opened position, typically 3.0 in.

The MBJS shall be designed to withstand the force effects for the strength limit state specified in Article 6.5.4 by applying the provisions of Articles 6.12 and 6.13, as applicable. All sections shall be compact, satisfying the provisions of Articles A6.1, A6.2, A6.3.2, and A6.3.3. MBJSes shall be designed to withstand the load combination for the Strength I limit state that is specified in Table 3.4.1-1 for the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4. Dead loads need not be included. Loads shall be distributed as specified in Article 14.5.6.9.5.

Anchors shall be investigated at the strength limit state due to vertical wheel loads without the horizontal wheel loads using the requirements of Article 6.10.10.4.3. The anchors shall be checked separately for the horizontal wheel loads at the strength limit state. In snow regions, another separate analysis shall be performed for the anchors for the snowplow load defined in Article 14.5.1.2. Pullout or breakout at the strength limit state under each of these loads shall be investigated by the latest ACI 318, Building Code Requirements for Structural Concrete, using the following resistance factors:

- For anchors governed by the steel, the resistance factors are:

$$\phi_{tension} = 0.80$$

$$\phi_{shear} = 0.75$$

- For anchors governed by the concrete, the load factors for Condition A, supplemental reinforcement in the failure area, are:

$$\phi_{A\ tension} = 0.85$$

$$\phi_{A\ shear} = 0.85$$

- For anchors governed by the concrete, the load factors for Condition B, no supplemental reinforcement, are:

$$\phi_{B\ tension} = 0.75$$

$$\phi_{B\ shear} = 0.75$$

C14.5.6.9.6

Anchorage calculations for strength and fatigue limit states are presented in Dexter et al. (2002). A prescriptive design was found that satisfies the strength and fatigue limit state requirements presented in this specification, including the snowplow load. This design may be adopted without presenting explicit calculations. This design consists of a steel edgebeam minimum thickness 0.375 in. with Grade 50 (50.0 ksi yield) 0.5-in. diameter welded headed anchors (studs) with length of anchor of 6.0 in. spaced every 12.0 in. The welded headed anchor shall have minimum cover depth of 3.0 in., except where over the support boxes, where the cover depth is 2.0 in.

Analyzing the centerbeam as a continuous beam over rigid supports has been found to give good agreement with measured strains for loads in the vertical direction. For loads in the horizontal direction, the continuous beam model is conservative. For the loads in the horizontal direction, more accurate results can be achieved by treating the centerbeams and support bars as a coplanar frame pinned at the ends of the support bars.

Maximum centerbeam stresses in interior spans are typically generated with one of the wheel loads centered in the span. However, if the span lengths are the same, the exterior spans (first from the curb) will typically govern the design. In an optimum design, this exterior span should be about ten percent less than typical interior spans.

The vertical and horizontal wheel loads are idealized as line loads along the centerlines of the centerbeams, i.e., it is not necessary to take into account eccentricity of the forces on the centerbeam. The maximum reaction of the centerbeam against the support bar is generated when the wheel load is centered over the support bar. This situation may govern for the throat of the centerbeam/support bar weld, for design of the stirrup of a SSB system, or for design of the support bar.

MBJSes installed on skewed structures may require special attention in the design process.

14.5.6.9.7—Fatigue Limit State Design Requirements

14.5.6.9.7a—General

MBJS structural members, including centerbeams, support bars, connections, bolted and welded splices, and attachments, shall meet the fracture toughness requirements in Article 6.6.2. Bolts subject to tensile fatigue shall satisfy the provisions of Article 6.13.2.10.3.

MBJS structural members, including centerbeams, support bars, connections, bolted and welded splices, and attachments, shall be designed for the fatigue limit state as specified in Article 6.6.1.2 and as modified and supplemented herein.

Each detail shall satisfy:

$$\Delta f \leq (\Delta F)_{TH} \quad (14.5.6.9.7a-1)$$

where:

- Δf = force effect, design live load stress range due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5, and calculated as specified in Article 14.5.6.9.7b (ksi)
- ΔF_{TH} = constant amplitude fatigue threshold taken from Table 6.6.1.2.3-1 for the detail category of interest (ksi)

The fatigue detail categories for the centerbeam-to-support-bar connection, shop splice, field splice, or other critical details shall be established by the fatigue testing as required by Article 14.5.6.9.3. All other details shall have been included in the test specimen. Details that did not crack during the fatigue test shall be considered noncritical. The fatigue detail categories for noncritical details shall be determined using Table 6.6.1.2.3-1.

Anchors and edgebeams shall be investigated for the fatigue limit state considering the force effects from vertical and horizontal wheel loads. Shear connectors and other anchors shall be designed for the fatigue limit state to resist the vertical wheel loads according to the provisions of Article 6.10.10.1.2 only for the Fatigue I case defined in Article 3.4.1. The force effects from the horizontal wheel loads need not be investigated for standard welded headed anchors.

Edgebeams shall be at least 0.375 in. thick. Edgebeams with standard welded headed anchors spaced at most every 12.0 in. need not be investigated for in-plane bending for the fatigue limit state.

C14.5.6.9.7a

The fatigue limit state strength of particular details in aluminum are approximately one-third the fatigue limit state strength of the same details in steel and, therefore, aluminum is typically not used in MBJSes.

Yield strength and fracture toughness and weld quality have not been noted as particular problems for MBJSes.

The design of the MBJS will typically be governed by the stress range at fatigue limit state critical details. The static strength limit state must also be checked according to the requirements of Article 14.5.6.9.6, but will typically not govern the design unless the total opening range and the support bar span is very large. Alternate design methods and criteria may be used if such methods can be shown through testing and/or analysis to yield fatigue-resistant and safe designs. The target reliability level for the fatigue limit state is 97.5 percent probability of no fatigue cracks over the lifetime of the MBJS.

Provisions are not included for a finite life fatigue limit state design (Fatigue II case, as defined in Article 3.4.1). Typically, most structures that require a modular expansion joint carry enough truck traffic to justify an infinite-life fatigue limit state design approach (Fatigue I case, as defined in Article 3.4.1). Furthermore, uncertainty regarding the number of axles per truck and the number of fatigue cycles per axle would make a finite life design approach difficult, and little cost is added to the MBJS by designing for infinite fatigue life.

The intent of this procedure is to assure that the stress range from the fatigue limit state load range is less than the constant amplitude fatigue limit (CAFL) and thereby ensuring essentially an infinite fatigue life.

Fatigue-critical MBJS details include:

- the connection between the centerbeams and the support bars;
- connection of any attachments to the centerbeams (e.g., horizontal stabilizers or outriggers); and
- shop and/or field splices in the centerbeams.

MBJS details can in many cases be clearly associated with analogous details in the bridge design specifications. In other cases, the association is not clear and must be demonstrated through full-scale fatigue testing.

The detail of primary concern is the connection between the centerbeams and the support bars. A typical full-penetration welded connection, which was shown previously, can be associated with Category C. Fillet welded connections have very poor fatigue resistance and should not be allowed.

The bolted connections in SSB MBJSes usually involve a yoke or stirrup through which the support bar slides and/or swivels. Bolted connections should be classified as a Category B detail with respect to the bending stress range in the centerbeam, when designed as slip-critical using high-strength bolts that are pretensioned per Table 11.5.6.4.1-1 of the *AASHTO LRFD Bridge Construction Specifications*. In addition, the nuts should be locked after installation to prevent loss of pretension in the bolts. Other bolted connections should be classified as a Category D detail. As in any construction, more than one bolt must be used in bolted connections.

Field-welded splices of the centerbeams and edgebeams are also prone to fatigue. In new construction, it may be possible to make a full-penetration welded splice in the field before the joint is lowered into the blockout. However, in reconstruction work, the joint is often installed in several sections at a time to maintain traffic. In these cases, the splice must be made after the joint is installed. Because of the difficulty in access and position, obtaining a full-penetration butt weld in the field after the joint is installed may be difficult, especially if there is more than one centerbeam. Partial-penetration splice joints have inherently poor fatigue resistance and should not be allowed.

Bolted splices have been used and no cracking of these bolted splice details has been reported. The bolted splice plates behave like a hinge, i.e., they do not take bending moments. As a result, such details are subjected only to small shear stress ranges and need not be explicitly designed for the fatigue limit state. However, the hinge in the span creates greater bending moments at the support bar connection, therefore, the span with the field splice must be much smaller than the typical spans to reduce the applied stress ranges at the support bar connection. Moreover, lost bolts have been reported in the field at these splice details, which if not detected in time can break the shear connection and result in cantilever centerbeams exhibiting unacceptable downward and rebound deflections under crossing vehicles. If bolted splices are used, the nuts should be locked after installation.

Thin stainless steel slider plates are often welded like cover plates on the support bars. The fatigue strength of the ends of cover plates is Category E. However, there have not been any reports of fatigue cracks at these slider plate details in MBJSes. The lack of problems may be because the support bar bending stress range is much lower at the location of the slider plate ends than at the centerbeam connection, which is the detail that typically governs the fatigue limit state design of the support bar. Also, it is possible that the fatigue strength is greater than that of conventional cover plates, perhaps because of the thinness of the slider plate. Often, the stainless steel plates are extended to the end of the support bars, eliminating the Category E detail at the termination.

The fatigue limit state of the support bars or centerbeams should also be checked at the location of welded attachments that react against the horizontal equidistant devices, if provided. In addition to checking the equidistant device attachments with respect to the stress range in the support bar, there is also some bending load in the attachment itself. The equidistant devices take part of the horizontal load, especially in SSB systems. The horizontal load is also transferred through friction in the bearings and springs of the centerbeam connection. However, since this transfer is influenced by the dynamic behavior of the MBJS, it is very difficult to quantify the load in the attachments.

These attachments are thoroughly tested in the Opening Movement Vibration (OMV) Test required in Appendix A19 of the *AASHTO LRFD Bridge Construction Specifications*. If the equidistant device attachments have no reported problems in the OMV Test, they need not be explicitly designed as a loaded attachment for the fatigue limit state. If there was a fatigue problem with these attachments, it would be discovered in the OMV Test.

14.5.6.9.7b—Design Stress Range

The design stress ranges, Δf , at all fatigue-critical details shall be obtained from structural analyses of the modular joint system due to the simultaneous application of vertical and horizontal axle loads specified in Article 14.5.6.9.4 and distributed as specified in Article 14.5.6.9.5. The MBJS shall be analyzed with a gap opening no smaller than the midrange configuration and no smaller than half of maximum gap opening. For each detail, the structural analysis shall include the worst-case position of the axle load to maximize the design stress range at that particular detail.

The nominal stress ranges, Δf , shall be calculated as follows for specific types of MBJS:

- SSB Systems
 - Centerbeam: The design bending stress range, Δf , in the centerbeam at a critical section adjacent to a welded or bolted stirrup shall be the sum of the stress ranges in the centerbeam resulting from horizontal and vertical bending at the critical section. The effects of stresses in any load-bearing attachments, such as the stirrup or yoke, need not be considered when calculating the stress range in the centerbeam. For bolted SSB systems, stress ranges shall be calculated on the net section if the connections are not designed as slip-critical using high-strength bolts.
 - Stirrup: The design stress range, Δf , in the stirrup or yoke shall consider the force effects of the vertical reaction force range between the centerbeam and support bar. The stress range shall be calculated by

C14.5.6.9.7b

Since the design axle load and distribution factors represent a “worst case,” the structural analysis for fatigue limit state design need not represent conditions worse than average. Therefore, for fatigue loading, the assumed gap can be equal to or greater than the midrange of the gap, typically 1.5 in., which is probably close to the mean or average opening. The gap primarily affects the support bar span.

See Article C14.5.6.9.6 for guidelines on the structural analysis. MBJSes installed on skewed structures may require special attention in the design process.

On structures with joint skews greater than 14 degrees, it can be shown that the wheels at either end of an axle will not roll over a particular centerbeam simultaneously. This asymmetric loading could significantly affect the stress range at fatigue-sensitive details, either favorably or adversely. Nevertheless, a skewed centerbeam span is subjected to a range of moments that includes the negative moment from the wheel in the adjoining span, followed or preceded by the positive moment from the wheel in the span.

The stress states at the potential critical locations in these connections are multiaxial and very complicated. Simplified assumptions are used to derive the design stress range at the details of interest for common types of MBJS. Experience has shown that these simplified assumptions are sufficient provided that the same assumptions are applied in calculating the applied stress range for plotting the fatigue test data from which the design detail category was determined.

The design stress range should be estimated at a critical section at the weld toe. For example, Figure C14.5.6.9.7b-1 shows a typical moment diagram for the support bar showing the critical section. The support bar design bending

assuming a load range in the stirrup that is greater than or equal to 30 percent of the total vertical reaction force range. The calculation of the design stress range in the stirrup or yoke need not consider the effects of stresses in the centerbeam. The effects of horizontal loads may be neglected in the fatigue limit state design of the stirrup.

- WMSB Systems

- Centerbeam Weld Toe Cracking, i.e., Type A Cracking: The design stress range, Δf , for Type A cracking shall include the concurrent effects of vertical and horizontal bending stress ranges in the centerbeam, S_{RB} , and the vertical stress ranges in the top of the weld, S_{RZ} , as shown in Figure 14.5.6.9.7b-1. The design stress range for Type A cracking shall be determined as:

$$\Delta f = \sqrt{S_{RB}^2 + S_{RZ}^2} \quad (14.5.6.9.7b-1)$$

in which:

$$S_{RB} = \frac{M_V}{S_{xcb}} + \frac{M_H}{S_{ycb}} \quad (14.5.6.9.7b-2)$$

$$S_{RZ} = \frac{M_{OT}}{S_{wtop}} + \frac{R_V}{A_{wtop}} \quad (14.5.6.9.7b-3)$$

$$M_{OT} = R_H d_{cb} \quad (14.5.6.9.7b-4)$$

where:

S_{RB} = combined bending stress range in the centerbeam (ksi)

M_V = vertical bending moment range in the centerbeam on the critical section located at the weld toe due to the vertical force range (kip-in.)

M_H = horizontal bending moment range in the centerbeam on the critical section located at the weld toe due to horizontal force range (kip-in.)

M_{OT} = overturning moment range from horizontal reaction force (kip-in.)

S_{xcb} = vertical section modulus to the bottom of the centerbeam (in.³)

S_{ycb} = horizontal section modulus of the centerbeam (in.³)

S_{RZ} = vertical stress range in the top of the centerbeam-to-support-bar weld from the concurrent reaction of the support beam (ksi)

stress range is a result of the sum of the bending moment created by the applied centerbeam reaction and the additional overturning moment developed by the horizontal force applied at the top of the centerbeam.

Figure C14.5.6.9.7b-1—Typical Moment Diagram for a Support Bar

It is conservative to estimate the moments at the centerline of the centerbeam as shown.

For all details except the WMSB centerbeam-to-support-bar connection, the design stress range can be calculated using the design moment at the location of interest. Special equations for calculating the stress range are provided for WMSB MBJSes. These special equations are based on cracking that has been observed in fatigue tests of WMSB MBJSes. For the case of welded multiple-support bar centerbeam-to-support-bar connections, the design stress range is obtained by taking the square root of the sum of the squares of the horizontal stress ranges in the centerbeam or support bar and vertical stress ranges in the weld. Note this method of combining the stresses ignores the contribution of shear stresses in the region. Shear stresses are ignored in this procedure since they are typically small and very difficult to determine accurately. More details are provided in Dexter et al. (1997).

- R_V = vertical reaction force range in the connection (kip)
 R_H = horizontal reaction force range in the connection (kip)
 d_{cb} = depth of the centerbeam (in.)
 S_{Wtop} = section modulus of the weld at the top for bending in the direction normal to the centerbeam axis (in.³)
 A_{Wtop} = area of weld at the top (in.²)

Figure 14.5.6.9.7b-1—Force Effects Associated with Type A Cracking

- Support Bar Weld Toe Cracking, i.e., Type B Cracking: The design stress range, Δf , for Type B cracking shall include the concurrent effects of vertical bending stress ranges in the support bar, S_{RB} , and the vertical stress ranges in bottom of the weld, S_{RZ} , as shown in Figure 14.5.6.9.7b-2. The design stress range, Δf , for Type B cracking shall be determined as:

$$\Delta f = \sqrt{S_{RB}^2 + S_{RZ}^2} \quad (14.5.6.9.7b-5)$$

in which:

$$S_{RB} = \frac{M_V}{S_{Xsb}} + \frac{1}{2} \frac{R_H \left(d_{cb} + h_w + \frac{1}{2} d_{sb} \right)}{S_{Xsb}} \quad (14.5.6.9.7b-6)$$

$$S_{RZ} = \frac{R_H (d_{cb} + h_w)}{S_{Wbot}} + \frac{R_V}{A_{Wbot}} \quad (14.5.6.9.7b-7)$$

where:

- S_{RB} = bending stress range in the support bar due to maximum moment including moment from vertical reaction and overturning at the connection (ksi)
- M_V = component of vertical bending moment range in the support bar due to the vertical reaction force range in the connection located on the critical section at the weld toe (kip-in.)
- S_{Xsb} = vertical section modulus of the support bar to the top of the support bar (in.³)
- h_w = height of the weld (in.)
- d_{sb} = depth of the support bar (in.)
- S_{RZ} = vertical stress range in the bottom of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection (ksi)
- S_{Wbot} = section modulus of the weld at the bottom for bending in the direction of the support bar axis (in.³)
- A_{Wbot} = area of weld at the bottom (in.²)

Figure 14.5.6.9.7b-2—Force Effects Associated with Type B Cracking

- Cracking through the Throat of the Weld, i.e., Type C Cracking: The design stress range, Δf , for Type C cracking is the vertical stress range, S_{RZ} , at the most narrow cross-section of the centerbeam-to-support-bar weld from the vertical and horizontal reaction force ranges in the connection, as shown in Figure 14.5.6.9.7b-3. The design stress range, Δf , for Type C cracking shall be determined as:

$$\Delta f = \frac{R_v}{A_{Wmid}} + \frac{R_H \left(d_{cb} + \frac{1}{2} h_w \right)}{S_{Wmid}} \quad (14.5.6.9.7b-8)$$

where:

S_{Wmid} = section modulus of the weld at the most narrow cross-section for bending in the direction normal to the centerbeam axis (in.³)

A_{Wmid} = minimum cross-sectional area of weld (in.²)

Figure 14.5.6.9.7b-3—Force Effects Associated with Type C Cracking

14.6—REQUIREMENTS FOR BEARINGS

14.6.1—General

Bearings may be fixed or movable as required for the bridge design. Movable bearings may include guides to control the direction of translation. Fixed and guided bearings shall be designed to resist all appropriate loads and restrain unwanted translation.

Unless otherwise noted, the resistance factor for bearings, ϕ , shall be taken as 1.0.

Bearings subject to net uplift at any limit state shall be secured by tie-downs or anchorages.

The magnitude and direction of movements and the loads to be used in the design of the bearing shall be clearly defined in the contract documents.

Combinations of different types of fixed or movable bearings should not be used at the same expansion joint, bent, or pier, unless the effects of differing deflection and rotation characteristics on the bearings and the structure are accounted for in the design.

Multi-rotational bearings conforming to the provisions of this Section should not be used where vertical loads are less than 20 percent of the vertical bearing capacity.

All bearings shall be evaluated for component and connection strength and bearing stability.

C14.6.1

Bearings support relatively large loads while accommodating large translation or rotations.

The behavior of bearings is quite variable, and there is very little experimental evidence to precisely define ϕ for each limit state. ϕ is taken to be equal to 1.0 in many parts of Article 14.6 where a more refined estimate is not warranted. The resistance factors are often embedded in the design equations and based on judgment and experience, but they are generally thought to be conservative.

Differing deflection and rotational characteristics may result in damage to the bearings and/or structure.

Bearings loaded to less than 20 percent of their vertical capacity require special design (FHWA, 1991).

Bearings can provide a certain degree of horizontal load resistance by limiting the radius of the spherical

Where two bearings are used at a support of box girders, the vertical reactions should be computed with consideration of torque resisted by the pair of bearings.

14.6.2—Characteristics

The bearing chosen for a particular application shall have appropriate load and movement capabilities. Table 14.6.2-1 and Figure 14.6.2-1 may be used as a guide when comparing the different bearing systems.

The following terminology shall apply to Table 14.6.2-1:

S	=	Suitable
U	=	Unsuitable
L	=	Suitable for limited applications
R	=	May be suitable, but requires special considerations or additional elements such as sliders or guideways
Long.	=	Longitudinal axis
Trans.	=	Transverse axis
Vert.	=	Vertical axis

surface. However, the ability to resist horizontal loads is a function of the vertical reaction on the bearing, which could drop during earthquakes or other extreme event loadings. In general, bearings are not recommended for horizontal to vertical load ratios of over 40 percent unless the bearings are intended to act as fuses or irreparable damage is permitted.

C14.6.2

Practical bearings will often combine more than one function to achieve the desired results. For example, a pot bearing may be combined with a PTFE sliding surface to permit translation and rotation.

Information in Table 14.6.2-1 is based on general judgment and observation, and there will obviously be some exceptions. Bearings listed as suitable for a specific application are likely to be suitable with little or no effort on the part of the Engineer other than good design and detailing practice. Bearings listed as unsuitable are likely to be marginal, even if the Engineer makes extraordinary efforts to make the bearing work properly. Bearings listed as suitable for limited application may work if the load and rotation requirements are not excessive.

Table 14.6.2-1—Bearing Suitability

Type of Bearing	Movement		Rotation about Bridge Axis Indicated			Resistance to Loads		
	Long.	Trans.	Long.	Trans.	Vert.	Long.	Trans.	Vert.
Plain Elastomeric Pad	S	S	S	S	L	L	L	L
Fiberglass-reinforced Pad	S	S	S	S	L	L	L	L

Figure 14.6.2-1—Common Bearing Types

14.6.3—Force Effects Resulting from Restraint of Movement at the Bearing

14.6.3.1—Horizontal Force and Movement

Horizontal forces and moments induced in the bridge by restraint of movement at the bearings shall be determined using the movements and bearing characteristics specified in Article 14.7. For bearings with elastomeric elements, these characteristics should include, but are not limited to, the consideration of increased shear modulus, G , at temperatures below 73°F.

Expansion bearings and their supports shall be designed in a manner such that the structure can undergo movements to accommodate the seismic and other extreme event displacement determined using the provisions in Section 3 without collapse. Adequate support length shall be provided for all bearings in accordance with Article 4.7.4.4.

The Engineer shall determine the number of bearings required to resist the loads specified in Section 3 with consideration of the potential for unequal participation due to tolerances, unintended misalignments, the capacity of the individual bearings, and the skew.

Consideration should be given to the use of field-adjustable elements to provide near simultaneous engagement of the intended number of bearings.

C14.6.3.1

Restraint of movement results in a corresponding force or moment in the structure. These force effects should be calculated taking into account the stiffness of the bridge and the bearings. The latter should be estimated by the methods outlined in Article 14.7. In some cases, the bearing stiffness depends on time and temperature, as well as on the movement. For example, the designer should take note that in cold temperatures which approach the appropriate minimum specified zone temperatures, the shear modulus, G , of an elastomer may be as much as four times that at 73°F. See Article 14.7.5.2 and AASHTO M 251M/M 251 for more information.

Expansion bearings should allow sufficient movement in their unrestrained direction to prevent premature failure due to seismic and other extreme event displacements.

Often, bearings do not resist load simultaneously, and damage to only some of the bearings at one end of a span is not uncommon. When this occurs, high load concentrations can result at the location of the undamaged bearings, which should be taken into account. The number of bearings engaged should be based on type, design, and detailing of the bearings used, and on the bridge skew. Skew angles under 15 degrees are usually ignored. Skew angles over 30 degrees are usually considered significant

At the strength and extreme event limit states, horizontal forces transmitted to the superstructure and substructure by bearings, H_{bu} , shall be taken as those induced by sliding friction, rolling friction, or shear deformation of a flexible element in the bearing.

Sliding friction force shall be taken as:

$$H_{bu} = \mu P_u \quad (14.6.3.1-1)$$

where:

H_{bu} = lateral load transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

μ = coefficient of friction

P_u = compressive force from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)

The force due to the deformation of an elastomeric element shall be taken as:

$$H_{bu} = GA \frac{\Delta_u}{h_{rt}} \quad (14.6.3.1-2)$$

where:

G = shear modulus of the elastomer (ksi)

A = plan area of elastomeric element or bearing (in.²)

Δ_u = shear deformation from applicable strength and extreme event load combinations in Table 3.4.1-1 (in.)

h_{rt} = total elastomer thickness (in.)

Strength and extreme event limit states rolling forces shall be determined by testing.

14.6.3.2—Moment

At the strength and extreme event limit states, both the substructure and superstructure shall be designed for the largest moment, M_u , transferred by the bearing.

For curved sliding bearings without a companion flat sliding surface, M_u , shall be taken as:

$$M_u = \mu P_u R \quad (14.6.3.2-1)$$

For curved sliding bearings with a companion flat sliding surface, M_u shall be taken as:

$$M_u = 2\mu P_u R \quad (14.6.3.2-2)$$

and need to be considered in analysis. Skewed bridges have a tendency to rotate under seismic loading, and bearings should be designed and detailed to accommodate this effect.

Horizontal forces transmitted to other bridge elements by bearings do not include forces associated with the deformations of stiff bearing elements or hard metal-on-metal contact of bearing components because provisions in Article 14.7 are intended to avoid such contact.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

Special consideration should be given to bearings that support large horizontal loads relative to the vertical load (SCEF, 1991).

Eq. 14.6.3.1-1 is a function of vertical forces and friction, and is a measure of the maximum horizontal force which could be transmitted to the superstructure or substructure before slip occurs. Eq. 14.6.3.1-2 is also a measure of the maximum transmitted horizontal force, but is dependant primarily upon the shear modulus (stiffness) of the elastomer and applied lateral forces such as braking.

C14.6.3.2

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

The tangential force in curved sliding bearings is caused by friction resistance at the curved surface, and it acts about the center of the curved surface. M_u is the moment due to this force that is transmitted by the bearing. The moment imposed on individual components of the bridge structure may be different from M_u depending on the location of the axis of rotation and can be calculated by a rational method.

where:

M_u = moment transmitted to the superstructure and substructure by bearings from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip-in.)

R = radius of curved sliding surface (in.)

For unconfined elastomeric bearings and pads, M_u shall be taken as:

$$M_u = 1.60(0.5E_c I) \frac{\theta_s}{h_{rt}} \quad (14.6.3.2-3)$$

where:

I = moment of inertia of plan shape of bearing (in.⁴)
 E_c = effective modulus of elastomeric bearing in compression (ksi)

θ_s = maximum service limit state design rotation angle specified in Article 14.4.2.1 (rad.)

h_{rt} = total elastomer thickness (in.)

For CDP, M_u shall be taken as:

$$M_u = 1.25(4.5 - 2.2S + 0.6\sigma_s) \frac{E_c I}{t_p} \theta_s \quad (14.6.3.2-4)$$

where:

E_c = uniaxial compressive stiffness of the cotton-duck bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi)

t_p = total thickness of CDP (in.)

S = shape factor of the CDP computed based on Eq. 14.7.5.1-1 and based on total pad thickness

σ_s = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)

θ_s = maximum rotation of the CDP from applicable service load combinations in Table 3.4.1-1 (rad.)

The load-deflection curve of an elastomeric bearing is nonlinear, so E_c is load-dependent. One acceptable approximation for the effective modulus is:

$$E_c = 4.8GS^2 \quad (C14.6.3.2-1)$$

where:

S = shape factor of an individual elastomer layer

G = shear modulus of the elastomer (ksi)

For a more precise approximation of effective modulus, the denominator of Eq. 14.7.5.3.3-15 may be used along with a calculated B_u from Eq. C14.7.5.3.3-7 or Eq. C14.7.5.3.3-8.

The factor 1.60 in Eq. 14.6.3.2-3 is an average multiplier on total load on the bearing to estimate a strength limit state load, M_u , based on a service limit state rotation, θ_s .

The factor 1.25 in Eq. 14.6.3.2-4 is a multiplier on total load on the bearing to estimate a strength limit state load, M_u , based on a service limit state rotation, θ_s , and stress, σ_s .

The rotational stiffness, K , of CDP is provided by:

$$K = (4.5 - 2.2S + 0.6\sigma_s) \frac{E_c I}{t_p} \quad (C14.6.3.2-2)$$

The moment, M_u , may be crucial for the design of CDPs, because movable CDPs are normally designed with PTFE sliding surfaces to develop the translational movement capacity. M_u in the bearing pad results in edge bearing stress on the PTFE in addition to the average compressive stress. The PTFE on CDPs is unconfined, and this moment may limit the bearing stress on the PTFE to a stress somewhat smaller than permitted on the CDP alone.

14.6.4—Fabrication, Installation, Testing, and Shipping

The provisions for fabrication, installation, testing, and shipping of bearings, specified in Section 18, “Bearing Devices,” of the *AASHTO LRFD Bridge Construction Specifications*, shall apply.

The setting temperature of the bridge or any component thereof shall be taken as the actual air temperature averaged over the 24-hour period immediately preceding the setting event.

14.6.5—Seismic and Other Extreme Event Provisions for Bearings

14.6.5.1—General

This Article shall apply to the analysis, design, and detailing of bearings to accommodate the effects of earthquakes and, as appropriate, other extreme events for which the horizontal loading component is very large.

These provisions shall be applied in addition to all other applicable code requirements. The bearing-type selection shall consider the criteria described in Article 14.6.5.3 in the early stages of design.

14.6.5.2—Applicability

These provisions shall apply to pin, roller, rocker, and bronze or copper-alloy sliding bearings, elastomeric bearings, spherical bearings, and pot and disc bearings in common slab-on-girder bridges, but not to isolation-type bearings or structural fuse bearings designed primarily for the effects of extreme event dynamic horizontal loadings.

Although the strategy taken herein assumes that inelastic action is confined to properly detailed hinge areas in substructures, alternative concepts that utilize movement at the bearings to dissipate extreme event horizontal and/or vertical forces may also be considered. Where alternate strategies may be used, all ramifications of the increased movements and the predictability of the associated forces and transfer of forces shall be considered in the design and details.

14.6.5.3—Design Criteria

The selection, and the seismic or other extreme event horizontal loading design of bearings shall be related to the strength and stiffness characteristics of both the superstructure and the substructure.

C14.6.4

Some jurisdictions have provided additional guidance beyond that provided in the *AASHTO LRFD Bridge Construction Specifications* with respect to the fabrication, installation, testing, and shipping of multi-rotational-type bearings (SCEF, 1991).

Setting temperature is used in installing expansion bearings.

An offset chart for girder erection and alignment of the bearings is recommended to account for uncertainty in the setting temperature at the time of design. Offset charts should be defined in appropriate increments and included in the design drawings so that the position of the bearing can be adjusted to account for differences between setting temperature and an assumed design installation temperature.

C14.6.5.1

Extreme events other than earthquakes for which the horizontal loading component is very large include vehicle collisions, ship collisions, and high-velocity winds.

C14.6.5.2

Provisions for the design, specification, testing, and acceptance of isolation bearings are given in the current *AASHTO Guide Specifications for Seismic Isolation Design*.

C14.6.5.3

The commentary provided below specifically addresses seismic design considerations. However, it is also applicable to other extreme event horizontal loadings such as vehicle and ship collisions, which are

Bearing design shall be consistent with the intended seismic or other extreme event response of the whole bridge system.

Where rigid-type bearings are used, the seismic or other horizontal extreme event forces from the superstructure shall be assumed to be transmitted through diaphragms or cross-frames and their connections to the bearings and then to the substructure without reduction due to local inelastic action along that load path. However, forces may be reduced in situations where the end-diaphragms in the superstructure have been specifically designed and detailed for inelastic action, in accordance with generally accepted provisions for ductile end-diaphragms.

As a minimum, bearings, restraints, and anchorages shall be designed to resist the forces specified in Article 3.10.9.

dynamic in nature but can have a very short duration. Accounting for the effects of other extreme events such as wind or waves may require special considerations that are not fully addressed in these specifications for bearing design.

Bearings have a significant effect on the overall seismic response of a bridge. They provide the seismic load transfer link between a stiff and massive superstructure and a stiff and massive substructure. As a result, very high (and difficult-to-predict) load concentrations can occur in the bearing components. The primary functions of the bearings are to resist the vertical loads due to dead load and live load and to allow for superstructure movements due to live load and temperature changes. Allowance for translation is made by means of rollers, rocker, or shear deformation of an elastomer, or through the provision of a sliding surface of bronze or copper alloy or PTFE. Allowance for rotation is made by hinges, confined or unconfined elastomers, or spherical sliding surfaces. Resistance to translation is provided by bearing components or additional restraining elements.

Historically, bearings have been very susceptible to seismic loads. Unequal loading during seismic events and much higher loads than anticipated have caused various types and levels of bearing damage. To allow movements, bearings often contain elements vulnerable to high loads and impacts.

The performance of bearings during past earthquakes needs to be evaluated in context with the overall performance of the bridge and the performance of the superstructure and substructure elements connected to the bearings. Rigid bearings have been associated with damage to the end cross-frames and the supporting pier or abutment concrete. In some cases, bearing damage and slippage has prevented more extensive damage.

The criteria for seismic design of bearings should consider the strength and stiffness characteristics of the superstructure and substructure. To minimize damage, the seismic load resisting system made of the end cross-frame or diaphragms, bearings, and substructure should allow a certain degree of energy dissipation, movement, or plastic deformation even if those effects are not quantified as they would be for seismic isolation bearings or structural fuses.

Based on their horizontal stiffness, bearings may be divided into four categories:

- rigid bearings that transmit seismic loads without any movement or deformations;
- deformable bearings that transmit seismic loads limited by plastic deformations or restricted slippage of bearing components;
- seismic isolation-type bearings that transmit reduced seismic loads, limited by energy dissipation; and

- structural fuses that are designed to fail at a prescribed load.

For the deformable-type bearing, limited and repairable bearing damage and displacement may be allowed for the design earthquake.

When both the superstructure and the substructure components adjacent to the bearing are very stiff, a deformable-type bearing should be considered.

Seismic isolation-type bearings should also be considered, and designed in accordance with the requirements of the current AASHTO *Guide Specifications for Seismic Isolation Design*.

Elastomeric bearings have been demonstrated to result in reduced force transmission to substructure.

A bearing may also be designed to act as a “structural fuse” that will fail at a predetermined load changing the articulation of the structure, possibly changing its period and hence seismic response, and probably resulting in increased movements. This strategy is permitted as an alternative to these provisions under Article 14.6.5.2. Such an alternative would require full consideration of forces and movements and of bearing repair/replacement details. It also requires the designer to address the inherent difficulty of detailing a structural element to fail reliably at predetermined load.

Elastomeric bearings having less than full rigidity, but not designed explicitly as seismic isolators or fuses, may be used under any circumstance. If used, they shall either be designed to accommodate imposed seismic or other horizontal extreme event loads, or, if survival of the elastomeric bearing itself is not required, other means such as restrainers, STUs, widened support lengths, or dampers shall be provided to prevent unseating of the superstructure.

14.7—SPECIAL DESIGN PROVISIONS FOR BEARINGS

14.7.1—Metal Rocker and Roller Bearings

14.7.1.1—General

The rotation axis of the bearing shall be aligned with the axis about which the largest rotations of the supported member occur. Provision shall be made to ensure that the bearing alignment does not change during the life of the bridge. Multiple roller bearings shall be connected by gearing to ensure that individual rollers remain parallel to each other and at their original spacing.

Metal rocker and roller bearings shall be detailed so that they can be easily inspected and maintained.

Rockers should be avoided wherever practical and, when used, their movements and tendency to tip under seismic actions shall be considered in the design and details.

C14.7.1.1

Cylindrical bearings contain no deformable parts and are susceptible to damage if the superstructure rotates about an axis perpendicular to the axis of the bearing. Thus, they are unsuitable for bridges in which the axis of rotation may vary significantly under different situations, such as bridges with a large skew. They are also unsuitable for use in seismic regions because the transverse shear caused by earthquake loading can cause substantial overturning moment.

Good maintenance is essential if mechanical bearings are to perform properly. Dirt attracts and holds moisture, which, combined with high local contact stresses, can promote stress corrosion. Metal bearings, in particular, must be designed for easy maintenance.

Rockers can be suitable for applications in which the horizontal movement of the superstructure, relative to the substructure, is well within the available movement range after consideration of other applicable movements.

14.7.1.2—Materials

Rocker and roller bearings shall be made of stainless steel conforming to ASTM A240/A240M, as specified in Article 6.4.7, or of structural steel conforming to AASHTO M 169 (ASTM A108), M 102M/M 102 (ASTM A668/A668M), or M 270M/M 270 (ASTM A709/A709M), Grades 36, 50, or 50W. Material properties of these steels shall be taken as specified in Tables 6.4.1-1 and 6.4.2-1.

14.7.1.3—Geometric Requirements

The dimensions of the bearing shall be chosen taking into account both the contact stresses and the movement of the contact point due to rolling.

Each individual curved contact surface shall have a constant radius. Bearings with more than one curved surface shall be symmetric about a line joining the centers of their two curved surfaces.

If pintles or gear mechanisms are used to guide the bearing, their geometry should be such as to permit free movement of the bearing.

Bearings shall be designed to be stable. If the bearing has two separate cylindrical faces, each of which rolls on a flat plate, stability may be achieved by making the distance between the two contact lines no greater than the sum of the radii of the two cylindrical surfaces.

14.7.1.4—Contact Stresses

At the service limit state, the contact load, P_s , shall satisfy:

- For cylindrical surfaces:

$$P_s \leq 8 \frac{WD_1}{\left(1 - \frac{D_1}{D_2}\right)} \left(\frac{F_y^2}{E_s}\right) \quad (14.7.1.4-1)$$

- For spherical surfaces:

$$P_s \leq 40 \left(\frac{D_1}{1 - \frac{D_1}{D_2}}\right)^2 \frac{F_y^3}{E_s^2} \quad (14.7.1.4-2)$$

where:

D_1 = diameter of the rocker or roller surface (in.)

C14.7.1.2

Carbon steel has been the traditional steel used in mechanical bearings because of its good mechanical properties. Surface hardening may be considered. Corrosion resistance is also important. The use of stainless steel for the contact surfaces may prove economical when life-cycle costs are considered. Weathering steels should be used with caution as their resistance to corrosion is often significantly reduced by mechanical wear at the surface.

C14.7.1.3

The choice of radius for a curved surface is a compromise: a large radius results in low contact stresses but large rotations of the point of contact and vice versa. The latter could be important if, for example, a rotational bearing is surmounted by a PTFE slider because the PTFE is sensitive to eccentric loading.

A cylindrical roller is in neutral equilibrium. The provisions for bearings with two curved surfaces achieves at least neutral, if not stable, equilibrium.

C14.7.1.4

The service limit state loads are limited so that the contact causes calculated shear stresses no higher than $0.55F_y$ or surface compression stresses no higher than $1.65F_y$. The maximum compressive stress is at the surface, and the maximum shear stress occurs just below it.

The formulas were derived from the theoretical value for contact stress between elastic bodies (Roark and Young, 1976). They are based on the assumption that the width of the contact area is much less than the diameter of the curved surface.

If two surfaces have curves of the opposite sign, the value of D_2 is negative. This would be an unusual situation in bridge bearings.

If careful inspection indicates that existing bearings which do not satisfy these provisions are performing well and there is no evidence of rutting or ridging, which may be evidence of local yielding, then reuse of the bearing may be viable. Evaluation of roller and rocker bearings with flat mating surfaces may proceed using the following historical provision:

Bearing per linear in. on expansion rockers and rollers at the service limit state shall not exceed the values obtained by the following formulas:

Diameters up to 25.0 in.:

$$p = \frac{F_y - 13}{20} (0.6d) \quad (\text{C14.7.1.4-1})$$

Diameters 25.0 to 125.0 in.:

$$p = \frac{F_y - 13}{20} 3\sqrt{d} \quad (\text{C14.7.1.4-2})$$

where:

- p = allowable bearing at the service limit state (kip/in.)
 d = diameter of rocker or roller (in.)
 F_y = specified minimum yield strength of the weakest steel at the contact surface (ksi)

If loads are increased significantly by the rehabilitation or the mating surface is curved, complying with the current provisions may be more appropriate.

The two diameters have the same sign if the centers of the two curved surfaces in contact are on the same side of the contact surface, such as is the case when a circular shaft fits in a circular hole.

D_2 = diameter of the mating surface (in.) taken as:

- Positive if the curvatures have the same sign, and
- Infinite if the mating surface is flat.

F_y = specified minimum yield strength of the weakest steel at the contact surface (ksi)

E_s = Young's modulus for steel (ksi)

W = width of the bearing (in.)

14.7.2—PTFE Sliding Surfaces

PTFE may be used in sliding surfaces of bridge bearings to accommodate translation or rotation. All PTFE surfaces other than guides shall satisfy the requirements specified herein. Curved PTFE surfaces shall also satisfy Article 14.7.3.

14.7.2.1—PTFE Surface

The PTFE surface shall be made from pure virgin PTFE resin satisfying the requirements of ASTM D4894 or D4895. It shall be fabricated as unfilled sheet, filled sheet, or fabric woven from PTFE and other fibers.

Unfilled sheets shall be made from PTFE resin alone. Filled sheets shall be made from PTFE resin uniformly blended with glass fibers, carbon fibers, or other chemically inert filler. The filler content shall not exceed 15 percent for glass fibers and 25 percent for carbon fibers.

Sheet PTFE may contain dimples to act as reservoirs for lubricant. Unlubricated PTFE may also contain dimples. Their diameter shall not exceed 0.32 in. at the surface of the PTFE, and their depth shall be not less than

C14.7.2

This Article does not cover guides. The friction requirements for guides are less stringent, and a wider variety of materials and fabrication methods can be used for them.

C14.7.2.1

PTFE may be provided in sheets or in mats woven from fibers. The sheets may be filled with reinforcing fibers to reduce creep—i.e., cold flow—and wear, or they may be made from pure resin. The friction coefficient depends on many factors, such as sliding speed, contact pressure, lubrication, temperature, and properties such as the finish of the mating surface (Campbell and Kong, 1987). The material properties that influence the friction coefficient are not well understood, but the crystalline structure of the PTFE is known to be important, and it is strongly affected by the quality control exercised during the manufacturing process.

Unfilled dimples can act as reservoirs for contaminants (dust, etc.) which can help to keep these contaminants from the contact surface.

14.7.2.3.2—Stainless Steel Mating Surfaces

The thickness of the stainless steel mating surface shall be at least 16-gauge when the maximum dimension of the surface is less than or equal to 12.0 in. and at least 13-gauge when the maximum dimension is larger than 12.0 in.

Backing plate requirements shall be taken as specified in Article 14.7.2.6.2.

14.7.2.4—Contact Pressure

The contact stress between the PTFE and the mating surface shall be determined at the service limit state using the nominal area.

The average contact stress shall be computed by dividing the load by the projection of the contact area on a plane perpendicular to the direction of the load. The contact stress at the edge shall be determined by taking into account the maximum moment transferred by the bearing assuming a linear distribution of stress across the PTFE.

Stresses shall not exceed those given in Table 14.7.2.4-1. Permissible stresses for intermediate filler contents shall be obtained by linear interpolation within Table 14.7.2.4-1.

C14.7.2.3.2

The minimum thickness requirements for the mating surface are intended to prevent it from wrinkling or buckling. This surface material is usually quite thin to minimize the cost of the highly finished mating surface. Some mating surfaces, particularly those with curved surfaces, are made of carbon steel on which a stainless steel weld is deposited. This welded surface is then finished and polished to achieve the desired finish. Some jurisdictions require a minimum thickness of 0.094 in. for welded overlay after grinding and polishing.

C14.7.2.4

The average contact stress shall be determined by dividing the load by the projection of the contact area onto a plane perpendicular to the direction of the load. The edge contact stress shall be determined based on the service limit state load and the maximum service limit state moment transferred by the bearing.

The contact pressure must be limited to prevent excessive creep or plastic flow of the PTFE, which causes the PTFE disc to expand laterally under compressive stress and may contribute to separation or bond failure. The lateral expansion is controlled by recessing the PTFE into a steel plate or by reinforcing the PTFE, but there are adverse consequences associated with both methods. Edge loading may be particularly detrimental because it causes large stress and potential flow in a local area near the edge of the material in hard contact between steel surfaces. The average and edge contact pressure in Table 14.7.2.4-1 are in appropriate proportions to one another relative to the currently available research. Better data may become available in the future. These are in the lower range of those used in Europe.

Table 14.7.2.4-1—Maximum Contact Stress for PTFE at the Service Limit State (ksi)

Material	Average Contact Stress (ksi)		Edge Contact Stress (ksi)	
	Permanent Loads	All Loads	Permanent Loads	All Loads
Unconfined PTFE:				
Unfilled Sheets	1.5	2.5	2.0	3.0
Filled Sheets with Maximum Filler Content	3.0	4.5	3.5	5.5
Confined Sheet PTFE	3.0	4.5	3.5	5.5
Woven PTFE Fiber over a Metallic Substrate	3.0	4.5	3.5	5.5
Reinforced Woven PTFE over a Metallic Substrate	4.0	5.5	4.5	7.0

14.7.2.5—Coefficient of Friction

The service limit design coefficient of friction of the PTFE sliding surface shall be taken as specified in Table 14.7.2.5-1. Intermediate values may be determined by interpolation. The coefficient of friction shall be determined by using the stress level associated with the applicable load combination specified in Table 3.4.1-1. Lesser values may be used if verified by tests.

Where friction is required to resist nonseismic loads, the design coefficient of friction under dynamic loading may be taken as not more than ten percent of the values listed in Table 14.7.2.5-1 for the bearing stress and PTFE type indicated.

The coefficients of friction in Table 14.7.2.5-1 are based on a 8.0 μ -in. finish mating surface. Coefficients of friction for rougher surface finishes must be established by test results in accordance with the *AASHTO LRFD Bridge Construction Specifications*, Chapter 18.

The contract documents shall require certification testing from the production lot of PTFE to ensure that the friction actually achieved in the bearing is appropriate for the bearing design.

C14.7.2.5

The friction factor decreases with lubrication and increasing contact stress but increases with sliding velocity (Campbell and Kong, 1987). The coefficient of friction also tends to increase at low temperatures. Static friction is larger than dynamic friction, and the dynamic coefficient of friction is larger for the first cycle of movement than it is for later cycles. Friction increases with increasing roughness of the mating surface and decreasing temperature. The friction factors used in the 17th edition of the *AASHTO Standard Specifications for Highway Bridges* are suitable for use with dimpled, lubricated PTFE. They are too small for the flat, dry PTFE commonly used in the United States. These Specifications have been changed to recognize this fact. Nearly all research to date has been performed on dimpled, lubricated PTFE. The coefficients of friction given in Table 14.7.2.5-1 are not applicable to high-velocity movements such as those occurring in seismic events. Seismic velocity coefficients of friction must be determined in accordance with the *AASHTO Guide Specifications for Seismic Isolation Design*. Coefficients of friction somewhat smaller than those given in Table 14.7.2.5-1 are possible with care and quality control.

Certification testing from the production lot is essential for PTFE sliding surfaces primarily to ensure that the friction actually achieved in the bearing is appropriate for the bearing design. Testing is the only reliable method for certifying the coefficient of friction and bearing behavior.

Contamination of the sliding surface with dirt and dust increases the coefficient of friction and increases the wear of the PTFE. To prevent contamination, the bearing should be sealed by the manufacturer and not separated at the construction site. To prevent contamination and gouging of the PTFE, the stainless steel should normally be on top and should be larger than the PTFE, plus its maximum travel.

Woven PTFE is sometimes formed by weaving pure PTFE strands with a reinforcing material. These reinforcing strands may increase the resistance to creep and cold flow and can be woven so that reinforcing strands do not appear on the sliding surface. This separation is necessary if the coefficients of friction provided in Table 14.7.2.5-1 are to be used.

If there is no lubricant in the dimples, the dimples tend to flatten out, filling the dimples and resulting in a surface much like unfilled PTFE.

Table 14.7.2.5-1—Design Coefficients of Friction—Service Limit State

	Pressure (ksi)	Coefficient of Friction			
		0.5	1.0	2.0	>3.0
Type PTFE	Temperature (°F)				
Dimpled Lubricated	68	0.04	0.030	0.025	0.020
	–13	0.06	0.045	0.040	0.030
	–49	0.10	0.075	0.060	0.050
Unfilled or Dimpled Unlubricated	68	0.08	0.070	0.050	0.030
	–13	0.20	0.180	0.130	0.100
	–49	0.20	0.180	0.130	0.100
Filled	68	0.24	0.170	0.090	0.060
	–13	0.44	0.320	0.250	0.200
	–49	0.65	0.550	0.450	0.350
Woven	68	0.08	0.070	0.060	0.045
	–13	0.20	0.180	0.130	0.100
	–49	0.20	0.180	0.130	0.100

14.7.2.6—Attachment

14.7.2.6.1—PTFE

Sheet PTFE confined in a recess in a rigid metal backing plate for one-half its thickness may be bonded or unbonded.

Sheet PTFE that is not confined shall be bonded to a metal surface or an elastomeric layer with a Shore A durometer hardness of at least 90 by an approved method.

Woven PTFE on a metallic substrate shall be attached to the metallic substrate by mechanical interlocking that can resist a shear force no less than 0.10 times the applied compressive force.

C14.7.2.6.1

Recessing is the most effective way of preventing creep in unfilled PTFE. The PTFE discs may also be bonded into the recess, but this is optional and the benefits are debatable. Bonding helps to retain the PTFE in the recess during the service life of the bridge, but it makes replacement of the disc more difficult. If the adhesive is not applied uniformly it can cause an uneven PTFE sliding surface that could lead to premature wear. Some manufacturers cut the PTFE slightly oversize and pre-cool it before installation because this results in a tighter fit at room temperature.

Sometimes PTFE is bonded to the top cover layer of an elastomeric bearing. This layer should be relatively thick and hard to avoid rippling of the PTFE (Roeder et al., 1987). PTFE must be etched prior to epoxy bonding in order to obtain good adhesion. However, ultraviolet light attacks the etching and can lead to delamination, so PTFE exposed to ultraviolet light should not be attached by bonding alone.

14.7.2.6.2—Mating Surface

The mating surface for flat sliding surfaces shall be attached to a backing plate by welding in such a way that it remains flat and in full contact with its backing plate throughout its service life. The weld shall be detailed to form an effective moisture seal around the entire perimeter of the mating surface to prevent interface corrosion. The attachment shall be capable of resisting the maximum friction force that can be developed by the bearing under service limit state load combinations. The welds used for the attachment shall be clear of the contact and sliding area of the PTFE surface.

C14.7.2.6.2

The restrictions on the attachment of the mating surface are primarily intended to ensure that the surface is flat and retains uniform contact with the PTFE at all times, without adversely affecting the friction of the surface or gouging or cutting the PTFE.

The mating surface of curved sliding surfaces should be machined to the required surface finish from a single piece.

Table 14.7.2.4-1, or on bronze by

Table 14.7.7.3-1 (ksi)

W = length of cylinder (in.)

ϕ = resistance factor, taken as 1.0

14.7.3.3—Resistance to Lateral Load

Where bearings are required to resist horizontal loads at the service limit state, an external restraint system shall be provided or:

- For a cylindrical sliding surface, the horizontal load shall satisfy:

$$H_s \leq 2RW\sigma_{ss} \sin(\psi - \beta - \theta_u) \sin \beta \quad (14.7.3.3-1)$$

- For a spherical surface, the horizontal load shall satisfy:

$$H_s \leq \pi R^2 \sigma_{ss} \sin(\psi - \beta - \theta_u) \sin \beta \quad (14.7.3.3-2)$$

in which:

$$\beta = \tan^{-1} \left(\frac{H_s}{P_D} \right) \quad (14.7.3.3-3)$$

and

$$\psi = \sin^{-1} \left(\frac{L}{2R} \right) \quad (14.7.3.3-4)$$

where:

H_s = horizontal load from applicable service load combinations in Table 3.4.1-1 (kip)

L = projected length of the sliding surface perpendicular to the rotation axis (in.)

P_D = compressive load at the service limit state (load factor = 1.0) due to permanent loads (kip)

R = radius of curved sliding surface (in.)

W = length of cylindrical surface (in.)

β = angle between the vertical and resultant applied load (rad.)

θ_u = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

σ_{ss} = maximum average contact stress at the service limit state permitted on PTFE by Table 14.7.2.4-1, or on bronze by Table 14.7.7.3-1 (ksi)

Ψ = subtended semiangle of the curved surface (rad.)

C14.7.3.3

The geometry of a curved bearing combined with gravity loads can provide considerable resistance to lateral load. An external restraint is often a more reliable method of resisting large lateral loads at the service and strength limit states, and at the extreme event limit state when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

The applied loads for determination of the angle β and the applied load check are at the service limit state because the stress limits, σ_{ss} , are service-based. The rotation at the strength limit state is utilized because bearings with curved sliding surfaces are susceptible to more serious consequences if overloaded or over rotated.

The geometry of a cylindrical sliding bearing is shown in the deformed position in Figure C14.7.3.3-1.

Figure C14.7.3.3-1—Bearing Geometry

14.7.4—Pot Bearings**14.7.4.1—General**

Where pot bearings are provided with a PTFE slider to provide for both rotation and horizontal movement, such sliding surfaces and any guide systems shall be designed in accordance with the provisions of Articles 14.7.2 and 14.7.9.

The rotational elements of the pot bearing shall consist of at least a pot, a piston, an elastomeric disc, and sealing rings.

For the purpose of establishing the forces and deformations imposed on a pot bearing, the axis of rotation shall be taken as lying in the horizontal plane at midheight of the elastomeric disc.

The minimum vertical load on a pot bearing should not be less than 20 percent of the vertical design load.

14.7.4.2—Materials

The elastomeric disc shall be made from a compound based on virgin natural rubber or virgin neoprene conforming to the requirements of Section 18.3 of the AASHTO *LRFD Bridge Construction Specifications*. The nominal hardness shall lie between 50 and 60 on the Shore A scale.

The pot and piston shall be made from structural steel conforming to AASHTO M 270M/M 270 (ASTM A709/A709), Grades 36, 50, or 50W; or from stainless steel conforming to ASTM A240/A240 M. The finish of surfaces in contact with the elastomeric pad shall be smoother than 60 μ -in. The yield strength and hardness of the piston shall not exceed that of the pot.

Brass sealing rings satisfying Articles 14.7.4.5.2 and 14.7.4.5.3 shall conform to ASTM B36 (half hard) for rings of rectangular cross-section, and Federal Specification QQB626, Composition 2, for rings of circular cross-section.

14.7.4.3—Geometric Requirements

The depth of the elastomeric disc, h_r , shall satisfy:

$$h_r \geq 3.33 D_p \theta_u \quad (14.7.4.3-1)$$

where:

D_p = internal diameter of pot (in.)

θ_u = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

The dimensions of the elements of a pot bearing shall satisfy the following requirements under the least favorable combination of strength limit state displacements and rotations:

C14.7.4.2

Softer elastomers permit rotation more readily and are preferred.

Corrosion-resistant steels, such as AASHTO M 270M/M 270 (ASTM A709/A709), Grade 50W, are not recommended for applications where they may come into contact with saltwater or be permanently damp, unless their whole surface is completely corrosion protected. Most pot bearings are machined from a solid plate, so use of high-strength steel to decrease the wall thickness results in only a very small reduction in volume of material used.

Other properties, such as corrosion resistance, ease of machining, electrochemical compatibility with steel girders, availability, and price should also be considered. The provision on relative hardness is mentioned to avoid wear or damage on the inside surface of the pot and the consequent risk of seal failure.

The choice of brass for sealing rings reflects present practice.

C14.7.4.3

The requirements of this Article are intended to prevent the seal from escaping and the bearing from locking up even under the most adverse conditions. Use of the design rotation, θ_u , means that the designer should account for both the anticipated movements due to loads and those due to fabrication and installation tolerances, including the rotation imposed on the bearing due to out-of-level of other bridge components, such as undersides of prefabricated girders, and permissible misalignments during construction. Vertical deflection caused by compressive load should also be taken into account because it will reduce the available clearance. Anchor bolts projecting above the base plate should be taken into consideration when clearance is determined.

- the pot shall be deep enough to permit the seal and piston rim to remain in full contact with the vertical face of the pot wall, and
- contact or binding between metal components shall not prevent further displacement or rotation.

Rotation capacity can be increased by using a deeper pot, a thicker elastomeric pad, and a larger vertical clearance between the pot wall and the piston or slider. The minimum thickness of the pad specified herein results in edge deflections due to rotation no greater than 15 percent of the nominal pad thickness. Figure C14.7.4.3-1 and Eqs. C14.7.4.3-1 and C14.7.4.3-2 may be used to verify clearance.

Figure C14.7.4.3-1—Pot Bearing—Critical Dimensions for Clearances

The pot cavity depth, h_{p1} , may be determined as:

$$h_{p1} \geq (0.5D_p \theta_u) + h_r + h_w \quad (\text{C14.7.4.3-1})$$

where:

h_r = depth of elastomeric disc (in.)

h_w = height from top of rim to underside of piston (in.)

The vertical clearance between top of piston and top of pot wall, h_{p2} , may be determined as:

$$h_{p2} \geq R_o \theta_u + 2\delta_u + 0.125 \quad (\text{C14.7.4.3-2})$$

where:

δ_u = vertical deflection from applicable strength load combinations in Table 3.4.1-1 (in.)

R_o = radial distance from center of pot to object in question (pot wall, anchor bolt, etc.) (in.)

Note that Eq. C14.7.4.3-1 does not contain any allowance for vertical deflection, δ_u . This omission is conservative. The design rotation, θ_u , already represents an extreme rotation for use with the strength limit state and requires no further factoring.

δ_u and θ_u may also be considered at the extreme event limit state.

Thicker pads with deeper pots cause smaller strains in the elastomer, and they appear to experience less wear and abrasion. Recessing of the rings into the pad is necessary for satisfactory pad performance, but it also decreases the effective thickness of the pad at that location. Further, the recess has sometimes been cut into the pad, and this cut appears to make the pad susceptible to additional damage. Therefore, it is generally better to use a deeper pot and thicker pad even though this leads to greater material and machining costs.

14.7.4.5.2—Rings with Rectangular Cross-Sections

Three rectangular rings shall be used. Each ring shall be circular in plan but shall be cut at one point around its circumference. The faces of the cut shall be on a plane at 45 degrees to the vertical and to the tangent of the circumference. The rings shall be oriented so that the cuts on each of the three rings are equally spaced around the circumference of the pot.

The width of each ring shall not be less than either $0.02 D_p$ or 0.25 in. and shall not exceed 0.75 in. The depth of each shall not be less than 0.2 times its width.

14.7.4.5.3—Rings with Circular Cross-Sections

One circular closed ring shall be used with an outside diameter of D_p . It shall have a cross-sectional diameter not less than either $0.0175 D_p$ or 0.15625 in.

14.7.4.6—Pot

The pot shall consist at least of a wall and base. All elements of the pot shall be designed to act as a single structural unit.

The thickness of a base bearing, t_b , directly against concrete or grout shall at minimum satisfy:

$$t_b \geq 0.06 D_p \text{ and} \quad (14.7.4.6-1)$$

$$t_b \geq 0.75 \text{ in.} \quad (14.7.4.6-2)$$

The thickness of a base bearing directly on steel girders or load distribution plates shall satisfy:

$$t_b \geq 0.04 D_p \text{ and} \quad (14.7.4.6-3)$$

$$t_b \geq 0.50 \text{ in.} \quad (14.7.4.6-4)$$

The minimum pot wall thickness, t_w , for an unguided sliding pot bearing shall satisfy:

$$t_w \geq \frac{D_p \sigma_s}{1.25 F_y} \quad (14.7.4.6-5)$$

and:

$$t_w \geq 0.75 \text{ in.} \quad (14.7.4.6-6)$$

where:

- t_w = pot wall thickness (in.)
- F_y = yield strength of the steel (ksi)
- D_p = internal diameter of pot (in.)
- σ_s = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

C14.7.4.6

Pots are constructed most reliably by machining from a single plate. For very large bearings, this may become prohibitively expensive, so fabrication by welding a ring to a base plate is implicitly accepted. However, the ring must be attached to the plate by a full-penetration weld because the wall is subject to significant bending moments where it joins the base plate. The quality of welding should be assured by quality control. The finished inside profile of the pot must satisfy the required shape and tolerances. Straightening and machining may be needed to rectify welding distortions.

The lower bounds on the thickness of the base plate are intended to provide some rigidity to counteract the effects of uneven bearing. If the base plate was to deform significantly, the volume of elastomer would be inadequate to fill the space in the pot, and hard contact could occur between some elements.

Eqs. 14.7.4.6-5 and 14.7.4.6-6 define minimum wall thickness requirements for unguided pot bearings. Eq. 14.7.4.6-5 is based upon hoop strength of the pot walls with the elastomeric disc under hydrostatic compressive stress. This equation is conservative for this application, because it neglects the beneficial effect of the bending strength and stiffness at the pot wall–base interface. However, this equation provides no lateral (horizontal) resistance to the bearing, and it is limited to unguided bearings (Stanton, 1999).

The limitation of Eq. 14.7.4.6-6 is based upon past manufacturing practice (SCEF, 1991).

The surface finish on the inside of the pot may have considerable impact on bearing performance. A smooth finish reduces rotational resistance and wear and abrasion of the elastomer. It may also improve the performance of the sealing rings, but at present there are no definitive limits as to what the surface finish should ideally be for good bearing performance. Metallization on the inside of the pot tends to cause a rougher surface finish, which leads

The wall thickness, t_w , and base thickness, t_b , of guided or fixed pots shall also satisfy the requirements of Eq. 14.7.4.7-1 for applicable strength and extreme event load combinations specified in Table 3.4.1-1 which are transferred by the piston to the pot wall.

14.7.4.7—Piston

The piston shall have the same plan shape as the inside of the pot. Its thickness shall be adequate to resist the loads imposed on it, but shall not be less than six percent of the inside diameter of the pot, D_p , except at the rim.

The perimeter of the piston shall have a contact rim through which horizontal loads may be transmitted. In circular pots, its surface may be either cylindrical or spherical. The body of the piston above the rim shall be set back or tapered to prevent binding. The height of the piston rim, w , shall be large enough to transmit the strength and extreme event limit states' horizontal forces between the pot and the piston.

Where a mechanical device is used to connect the superstructure to the substructure, it shall be designed to resist the greater of H_u at the support for the strength and extreme event limit states, or 15 percent of the maximum vertical load at the service limit state at that location.

Pot bearings subjected to lateral loads shall be proportioned so that the thickness of the pot wall, t_w , and the pot base, t_b , shall satisfy:

$$t_w, t_b \geq \sqrt{\frac{25H_u \theta_u}{F_y}} \quad (14.7.4.7-1)$$

Pot bearings that transfer load through the piston shall satisfy:

$$h_w \geq \frac{1.5H_u}{D_p F_y} \quad (14.7.4.7-2)$$

$$h_w \geq 0.125 \text{ in., and} \quad (14.7.4.7-3)$$

$$h_w \geq 0.03D_p \quad (14.7.4.7-4)$$

where:

- H_u = lateral load from applicable strength and extreme event load combinations in Table 3.4.1-1 (kip)
- θ_u = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)
- F_y = yield strength of steel (ksi)
- D_p = internal diameter of pot (in.)
- h_w = height from top of rim to underside of piston (in.)
- t_w = pot wall thickness (in.)
- t_b = pot base thickness (in.)

to significant increases in damage under cyclic rotation; as a result, metallization may not be a good method of protection.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

C14.7.4.7

The required piston thickness is controlled by rigidity and strength. A central internal guide bar fitted in a slot in the piston causes bending moments that are largest where the piston is weakest. In this case, the piston must also be thick enough to supply an adequate grip length for any bolts used to secure the guide bar.

If the piston rotates while a horizontal load is acting, the piston rim will be subject to bearing stresses due to horizontal load and to shear forces. If the rim surface is cylindrical, contact between it and the pot wall will theoretically be along a line when the piston rotates. In practice, some localized yielding is inevitable. If the rim surface forms part of a sphere, the contact area will be finite, providing less potential for local damage. Damage to the pot wall should be avoided because it will jeopardize the effectiveness of the seal. The dimensions of the rim depend on the contact area, and because this is uncertain, the rim should be designed conservatively. Eq. 14.7.4.7-4 is based on consideration of bearing stresses alone, using a strength limit state horizontal force of 0.15 times the vertical service limit state load, $F_y = 50.0$ ksi and $\phi = 0.9$.

The 15 percent factor applied to the service limit state vertical load, embedded in Eq. 14.7.4.7-4 and used in the design of mechanical devices that connect the superstructure to the substructure, approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted. θ_u may also be considered at the extreme event limit state.

The clearance between piston and pot is critical to the proper functioning of the bearing. In most bearings the finished clearance, after anticorrosion coatings have been applied, should be about 0.02 to 0.04 in., a range that is easily achievable. The equation for minimum clearance is based on geometry. Eq. 14.7.4.7-5 may occasionally produce a negative number; however, in these instances the minimum value of 0.02 in. controls.

The diameter of the piston rim shall be the inside diameter of the pot less a clearance, c . The clearance, c , shall be as small as possible in order to prevent escape of the elastomer but not less than 0.02 in. If the surface of the piston rim is cylindrical, the clearance shall satisfy:

$$c \geq \theta_u \left(h_w - \frac{D_p \theta_u}{2} \right) \quad (14.7.4.7-5)$$

where:

D_p = internal diameter of pot (in.)
 h_w = height from top of rim to underside of piston (in.)
 θ_u = maximum strength limit state design rotation angle specified in Article 14.4.2.2.1 (rad.)

14.7.5—Steel-Reinforced Elastomeric Bearings— Method B

14.7.5.1—General

Steel-reinforced elastomeric bearings may be designed using either of two methods commonly referred to as Method A and Method B. Where the provisions of this Article are used, the component shall be taken to meet the requirements of Method B. Where the provisions of Article 14.7.6 are used, the component shall be taken to meet the requirements of Method A.

Steel-reinforced elastomeric bearings shall consist of alternate layers of steel reinforcement and elastomer bonded together. In addition to any internal reinforcement, bearings may have external steel load plates bonded to either or both the upper or lower elastomer layers.

Tapered elastomer layers shall not be used. All internal layers of elastomer shall be of the same thickness. The top and bottom cover layers shall be no thicker than 70 percent of the internal layers, or $5/16$ in., whichever is greater. Minimum edge cover for steel reinforcement shall be $1/4$ in.

The shape factor of a layer of an elastomeric bearing, S_i , shall be taken as the plan area of the layer divided by the area of perimeter free to bulge. Unless noted otherwise, the values of S_i and h_{ri} to be used in Articles 14.7.5 and 14.7.6 for steel-reinforced elastomeric bearing design shall be that for an internal layer. For rectangular bearings without holes, the shape factor of a layer may be taken as:

$$S_i = \frac{LW}{2h_{ri}(L + W)} \quad (14.7.5.1-1)$$

C14.7.5.1

The stress limits associated with Method A usually result in a bearing with a lower capacity than a bearing designed using Method B. This increased capacity resulting from the use of Method B requires additional testing and quality control.

Steel-reinforced elastomeric bearings are treated separately from other elastomeric bearings because of their greater strength and superior performance in practice (Roeder et al., 1987; Roeder and Stanton, 1991). The critical parameter in their design is the shear strain in the elastomer at its interface with the steel plates. Axial load, rotation, and shear deformations all cause such shear strains. The design method (Method B) described in this Section accounts directly for those shear strains and provides a versatile means of allowing for different combinations of loadings.

Tapered layers cause larger shear strains and bearings made with them fail prematurely due to delamination or rupture of the reinforcement. All internal layers should be the same thickness because the strength and stiffness of the bearing in resisting compressive load are controlled by the thickest layer.

The shape factor, S_i , is defined in terms of the gross plan dimensions of layer i . Refinements to account for the difference between gross dimensions and the dimensions of the reinforcement are not warranted because quality control on elastomer thickness has a more dominant influence on bearing behavior. Holes are strongly discouraged in steel-reinforced bearings. However, if holes are used, their effect should be accounted for when calculating the shape factor because they reduce the loaded area and increase the area free to bulge. Suitable shape factor formulas are:

where:

- L = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
- W = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)
- h_{ri} = thickness of i th elastomeric layer (in.)

For circular bearings without holes, the shape factor of a layer may be taken as:

$$S_i = \frac{D}{4h_{ri}} \quad (14.7.5.1-2)$$

where:

- D = diameter of the projection of the loaded surface of the bearing in the horizontal plane (in.)

- For rectangular bearings:

$$S_i = \frac{LW - \sum \frac{\pi}{4} d^2}{h_{ri} [2L + 2W + \sum \pi d]} \quad (C14.7.5.1-1)$$

- For circular bearings:

$$S_i = \frac{D^2 - \sum d^2}{4h_{ri} (D + \sum d)} \quad (C14.7.5.1-2)$$

where:

- d = the diameter of the hole or holes in the bearing (in.)

Large steel-reinforced elastomeric bearings (defined as those which are thicker than 8 in. or having a plan area greater than 1,000 in.²) are more difficult to fabricate than small ones. The consequences of failure are also likely to be more severe in a large bearing. As such, large bearings should be designed according to Method B, which requires additional testing and quality control.

14.7.5.2—Material Properties

The shear modulus of the elastomer at 73°F shall be used as the basis for design.

The elastomer shall have a specified shear modulus between 0.080 and 0.175 ksi. It shall conform to the requirements of Section 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251M/M 251.

The acceptance criteria in AASHTO M 251M/M 251 shall be followed which:

- permits a variation of ± 15 percent from the value specified for shear modulus according to the first and second paragraphs of this Article, and
- does not permit a shear modulus below 0.080 ksi.

For design purposes, the shear modulus shall be taken as the least favorable of the values in the ranges described above.

Other properties, such as creep deflection, should be obtained from Table 14.7.6.2-1 or from tests conducted using AASHTO M 251M/M 251.

C14.7.5.2

Shear modulus, G , is the most important material property for design, and it is, therefore, the primary means of specifying the elastomer. Hardness has been widely used in the past, and is still permitted for Method A design, because the test for it is quick and simple. However, the results obtained from it are variable and correlate only loosely with shear modulus.

Materials with a specified shear modulus greater than 0.175 ksi are prohibited because they generally have a smaller elongation at break and greater stiffness and greater creep than their softer counterparts. This inferior performance is generally attributed to the larger amounts of filler present. Their fatigue behavior does not differ in a clearly discernible way from that of softer materials.

The least favorable value for the shear modulus used in design calculations is dependent upon whether the parameter being calculated is conservatively estimated by over- or under-estimating the shear modulus. The forgiving nature of elastomers tends to compensate for service and installation conditions which are less than ideal. (See Article 14.7.5.3.2.) Despite this, the designer should be cautious about specifying a shear modulus which is at or near the specified upper or lower bounds of 0.175 ksi and 0.080 ksi, respectively.

For the purposes of bearing design, all bridge sites shall be classified as being in temperature Zones A, B, C, D, or E for which design data are given in Table 14.7.5.2-1. In the absence of more precise information, Figure 14.7.5.2-1 may be used as a guide in selecting the zone required for a given region.

Bearings shall be made from AASHTO low-temperature grades of elastomer as defined in Section 18 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251M/M 251. The minimum grade of elastomer required for each low-temperature zone shall be taken as specified in Table 14.7.5.2-1.

Any of the three design options listed below may be used:

- Specify the elastomer with the minimum low-temperature grade indicated in Table 14.7.5.2-1 and determine the shear force transmitted by the bearing as specified in Article 14.6.3.1;
- Specify the elastomer with the minimum low-temperature grade for use when special force provisions are incorporated in the design and provide a low-friction sliding surface, in which case the bridge shall be designed to withstand twice the design shear force specified in Article 14.6.3.1; or
- Specify the elastomer with the minimum low-temperature grade for use when special force provisions are incorporated in the design but do not provide a low-friction sliding surface, in which case the components of the bridge shall be designed to resist four times the design shear force, as specified in Article 14.6.3.1.

The zones are defined by their extreme low temperatures or the largest number of consecutive days when the temperature does not rise above 32°F, whichever gives the more severe condition.

Shear modulus increases as the elastomer cools, but the extent of stiffening depends on the elastomer compound, time, and temperature. It is, therefore, important to specify a material with low-temperature properties that are appropriate for the bridge site. In order of preference, the low-temperature classification should be based on:

- the 50-year temperature history at the site,
- a statistical analysis of a shorter temperature history, or
- Figure 14.7.5.2-1.

Table 14.7.5.2-1 gives the minimum elastomer grade to be used in each zone. A grade suitable for a lower temperature may be specified by the Engineer, but improvements in low-temperature performance can often be obtained only at the cost of reductions in other properties. This low-temperature classification is intended to limit the force on the bridge substructure to 1.5 times the service limit state design force under extreme environmental conditions.

Figure 14.7.5.2-1—Temperature Zones

14.7.5.3.3—Combined Compression, Rotation, and Shear

Combinations of axial load, rotation, and shear at the service limit state shall satisfy:

$$(\gamma_{a,st} + \gamma_{r,st} + \gamma_{s,st}) + 1.75(\gamma_{a,cy} + \gamma_{r,cy} + \gamma_{s,cy}) \leq 5.0 \quad (14.7.5.3.3-1)$$

The static component of γ_a shall also satisfy:

$$\gamma_{a,st} \leq 3.0 \quad (14.7.5.3.3-2)$$

where:

- γ_a = shear strain caused by axial load
- γ_r = shear strain caused by rotation
- γ_s = shear strain caused by shear displacement

Subscripts “st” and “cy” indicate static and cyclic loading, respectively. Cyclic loading shall consist of loads induced by traffic. All other loads may be considered static. In rectangular bearings, the shear strains shall be evaluated for rotation about the axis which is parallel to the transverse axis of the bridge. Evaluation of shear strains for rotation about the axis which is parallel to the longitudinal axis of the bridge should also be considered. For circular bearings, the rotations about two primary orthogonal axes shall be added vectorially, and the shear strains shall be evaluated using the largest sum.

The shear strains, γ_a , γ_r , and γ_s , shall be established by rational analysis, in lieu of which the following approximations are acceptable.

The shear strain due to axial load may be taken as:

$$\gamma_a = D_a \frac{\sigma_s}{GS_i} \quad (14.7.5.3.3-3)$$

in which, for a rectangular bearing:

$$D_a = 1.4 \quad (14.7.5.3.3-4)$$

and, for a circular bearing:

$$D_a = 1.0 \quad (14.7.5.3.3-5)$$

where:

- D_a = dimensionless coefficient used to determine shear strain due to axial load
- G = shear modulus of the elastomer (ksi)
- S_i = shape factor of the i th internal layer of an elastomeric bearing

C14.7.5.3.3

Elastomers are almost incompressible, so when a steel-laminated bearing is loaded in compression the elastomer expands laterally due to the Poisson effect. That expansion is partially restrained by the steel plates to which the elastomer layers are bonded, and the restraint results in bulging of the layers between the plates. The bulging creates shear stresses at the bonded interface between the elastomer and steel. If they become large enough, they can cause shear failure of the bond or the elastomer adjacent to it. This is the most common form of damage in steel-laminated elastomeric bearings and is why limitations on the shear strain in the elastomer dominate the design requirements.

The cyclic components of the loading are multiplied by an amplification factor of 1.75 in Eq. 14.7.5.3.3-1. This reflects the results of tests that showed that cyclic shear strain causes more debonding damage than a static shear strain of the same amplitude. This approach of using an explicit summation of the shear strain components coupled with an amplification factor on cyclic components is found in other specifications, such as the European EN 1337.

In some cases, the rotations due to dead and live load will have opposite signs, in which case use of the amplification factor of 1.75 could lead to an amplified rotation that is artificially low. This is clearly not consistent with the intent of the amplification factor. In cases where the sense of the loading components in the critical combination is unclear, the sum of the absolute value should be used.

For rectangular bearings, separate evaluations about each primary rotation axis (parallel to the transverse global axis and parallel to the longitudinal global axis of the bridge) may be necessary and appropriate, such as for structures with significant skew. Where rectangular bearings are evaluated about an axis parallel to the global longitudinal axis of the bridge, the definitions of L and W should be interchanged.

For highly skewed or curved bridges, the girder ends will significantly rotate in both bending and torsion. Circular bearings offer a good alternative.

The constants 1.4 assigned to D_a and 0.5 assigned to D_r for rectangular bearings represent simplified values for determining shear strains which are evaluated for rotation about an axis which is parallel to the transverse axis of the bridge. They were derived from procedures suggested by Stanton et al. (2007). D_a and D_r may alternatively be determined with Eqs. C14.7.5.3.3-1 through C14.7.5.3.3-6 about either primary orthogonal axis for rectangular bearings.

$$D_a = \max \left[d_{a1}, \left(d_{a2} + d_{a3} \times \frac{L}{W} \right) \right] \quad (C14.7.5.3.3-1)$$

σ_s = average compressive stress due to total static or cyclic load from applicable service load combinations in Table 3.4.1-1 (ksi)

The shear strain due to rotation for a rectangular bearing may be taken as:

$$\gamma_r = D_r \left(\frac{L}{h_{rt}} \right)^2 \frac{\theta_s}{n} \quad (14.7.5.3.3-6)$$

in which:

$$D_r = 0.5 \quad (14.7.5.3.3-7)$$

and, for a circular bearing:

$$\gamma_r = D_r \left(\frac{D}{h_{rt}} \right)^2 \frac{\theta_s}{n} \quad (14.7.5.3.3-8)$$

in which:

$$D_r = 0.375 \quad (14.7.5.3.3-9)$$

where:

- D = diameter of the bearing (in.)
- D_r = dimensionless coefficient used to determine shear strain due to rotation
- h_{rt} = thickness of i th internal elastomeric layer (in.)
- L = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
- n = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter n may be increased by one-half for each such exterior layer.
- θ_s = maximum static or cyclic service limit state design rotation angle of the elastomer specified in Article 14.4.2.1 (rad.)

The shear strain due to shear deformation of any bearing may be taken as:

$$\gamma_s = \frac{\Delta_s}{h_{rt}} \quad (14.7.5.3.3-10)$$

where:

- h_{rt} = total elastomer thickness (in.)
- Δ_s = maximum total static or cyclic shear deformation

$$D_r = \frac{1.552 - 0.627\lambda}{2.233 + 0.156\lambda + \frac{L}{W}} \leq 0.5 \quad (C14.7.5.3.3-2)$$

in which:

$$d_{a1} = 1.06 + 0.210\lambda + 0.413\lambda^2 \quad (C14.7.5.3.3-3)$$

$$d_{a2} = 1.506 - 0.071\lambda + 0.406\lambda^2 \quad (C14.7.5.3.3-4)$$

$$d_{a3} = -0.315 + 0.195\lambda - 0.047\lambda^2 \quad (C14.7.5.3.3-5)$$

$$\lambda = S_i \sqrt{\frac{3G}{K}} \quad (C14.7.5.3.3-6)$$

where:

- K = bulk modulus (ksi)
- L = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
- W = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)
- λ = compressibility index

In the absence of better information, the bulk modulus, K , may be taken as 450 ksi for all elastomers permissible under this specification for use in steel-reinforced elastomeric bearings.

The compressibility index, λ , represents the effect of finite bulk stiffness of the rubber. For conventional bearings it makes little difference, but in high shape factor bearings it reduces the stiffness below the value that would be computed using an incompressible model (i.e., with $\lambda = 0$).

of the elastomer from applicable service load combinations in Table 3.4.1-1 (in.)

In each case, the static and cyclic components of the shear strain shall be considered separately and then combined using Eq. 14.7.5.3.3-1.

In bearings with externally bonded steel plates on both top and bottom, the peak hydrostatic stress shall satisfy:

$$\sigma_{hyd} \leq 2.25G \quad (14.7.5.3.3-11)$$

in which:

$$\sigma_{hyd} = 3GS_i^3 \frac{\theta_s}{n} C_\alpha \quad (14.7.5.3.3-12)$$

$$C_\alpha = \frac{4}{3} \left[\left(\alpha^2 + \frac{1}{3} \right)^{1.5} - \alpha(1 - \alpha^2) \right] \quad (14.7.5.3.3-13)$$

$$\alpha = \frac{\varepsilon_a}{S_i \theta_s} \quad (14.7.5.3.3-14)$$

$$\varepsilon_a = \frac{\sigma_s}{3B_a G S_i^2} \quad (14.7.5.3.3-15)$$

for rectangular bearings:

$$B_a = 1.6 \quad (14.7.5.3.3-16)$$

and, for circular bearings:

$$B_a = 1.6 \quad (14.7.5.3.3-17)$$

where:

- B_a = dimensionless coefficient used to determine peak hydrostatic stress
- ε_a = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)
- θ_s = total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.)
- σ_s = total of static and cyclic average compressive stress in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)

For values of α greater than one-third, the hydrostatic stress is compressive, so Eq. 14.7.5.3.3-11 is satisfied automatically and no further evaluation is necessary.

Previous editions of these Specifications contained provisions to prevent net upward movement of any point on the bearing. Prior research (Stanton et al., 2007) has shown that, if the bearing is not equipped with bonded external plates, the sole plate can lift away from the bearing without causing any tension in the elastomer. Furthermore, the compression effects are slightly less severe than in a bearing that is identical except for the presence of bonded external plates, and is subjected to the same loading combination. Thus the “no-liftoff” provisions have been removed.

However, in a bearing equipped with external plates, upward movement of part of the plate can cause internal rupture due to hydrostatic tension. Provisions have been added to address this case. It is expected to control only rarely, and when it does, it is likely to do so during construction, when the axial load is light and the rotation, due to pre-camber, is large. For the construction load case, the cyclic components of the loading will be zero. For bearings with external plates, Eqs. 14.7.5.3.3-1 and 14.7.5.3.3-11 should be checked under all critical loading conditions, including construction, and about both strong and weak axes of rectangular bearings when necessary and appropriate.

The constant 1.6 assigned to B_a for rectangular and circular bearings represents a simplified value for determining compressive strain due to a purely axial load (Eq. 14.7.5.3.3-15). This also applies to hydrostatic tension which is evaluated for rotation about an axis, which is parallel to the transverse axis of the bridge. It was derived from procedures suggested by Stanton et al. (2007). A more precise value of B_a (and consequently more precise value of E and axial strain) may alternatively be determined with Eqs. C14.7.5.3.3-7 or C14.7.5.3.3-8 about either primary orthogonal axis.

For rectangular bearings:

$$B_a = (2.31 - 1.86\lambda) + (-0.90 + 0.96\lambda) \times \left[1 - \min\left(\frac{L}{W}, \frac{W}{L}\right) \right]^2 \quad (C14.7.5.3.3-7)$$

and, for circular bearings:

$$B_a = \frac{2}{1 + 2\lambda^2} \quad (C14.7.5.3.3-8)$$

Tests have shown that sharp edges on the internal steel reinforcement layers cause stress concentrations in

14.7.5.3.4—Stability of Elastomeric Bearings

Bearings shall be investigated for instability at the service limit state load combinations specified in Table 3.4.1-1.

Bearings satisfying Eq. 14.7.5.3.4-1 shall be considered stable, and no further investigation of stability is required.

$$2A \leq B \quad (14.7.5.3.4-1)$$

in which:

$$A = \frac{1.92 \frac{h_{rt}}{L}}{\sqrt{1 + \frac{2.0L}{W}}} \quad (14.7.5.3.4-2)$$

$$B = \frac{2.67}{(S_i + 2.0) \left(1 + \frac{L}{4.0W} \right)} \quad (14.7.5.3.4-3)$$

where:

- G = shear modulus of the elastomer (ksi)
- h_{rt} = total elastomer thickness (in.)
- L = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
- S_i = shape factor of the i th internal layer of an elastomeric bearing
- W = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)

For a rectangular bearing where L is greater than W , stability shall be investigated by interchanging L and W in Eqs. 14.7.5.3.4-2 and 14.7.5.3.4-3.

For circular bearings, stability may be investigated by using the equations for a square bearing with $W = L = 0.8D$.

For rectangular bearings not satisfying Eq. 14.7.5.3.4-1, the stress due to the total load shall satisfy Eq. 14.7.5.3.4-4 or 14.7.5.3.4-5.

the elastomer and promote the onset of debonding. The internal steel reinforcement layers should be deburred or otherwise rounded prior to molding the bearing. The design values in Eq. 14.7.5.3.3-1 are consistent with this procedure.

C14.7.5.3.4

The average compressive stress is limited to half the predicted buckling stress. The latter is calculated using the buckling theory developed by Gent, modified to account for changes in geometry during compression, and calibrated against experimental results (Gent, 1964; Stanton et al., 1990). This provision will permit taller bearings and reduced shear forces compared to those permitted under the 17th edition of the AASHTO *Standard Specifications for Highway Bridges* (2002).

A negative or infinite limit from Eq. 14.7.5.3.4-5 indicates that the bearing is stable and is not dependent on σ_s .

- If the bridge deck is free to translate horizontally:

$$\sigma_s \leq \frac{GS_f}{2A - B} \quad (14.7.5.3.4-4)$$

- If the bridge deck is fixed against horizontal translation:

$$\sigma_s \leq \frac{GS_f}{A - B} \quad (14.7.5.3.4-5)$$

If the value $A - B \leq 0$, the bearing is stable and is not dependent on σ_s .

Eq. 14.7.5.3.4-4 corresponds to buckling in a sideways mode and is relevant for bridges in which the deck is not rigidly fixed against horizontal translation at any point. This may be the case in many bridges for transverse translation perpendicular to the longitudinal axis. If one point on the bridge is fixed against horizontal movement, the sideways buckling mode is not possible, and Eq. 14.7.5.3.4-5 should be used. This freedom to move horizontally should be distinguished from the question of whether the bearing is subject to shear deformations relevant to Articles 14.7.5.3.2 and 14.7.5.3.3. In a bridge that is fixed at one end, the bearings at the other end will be subjected to imposed shear deformation but will not be free to translate in the sense relevant to buckling due to the restraint at the opposite end of the bridge.

14.7.5.3.5—Reinforcement

The minimum thickness of steel reinforcement, h_s , shall be 0.0747 in., as specified in Article 4.2 of AASHTO M 251M/M 251.

The thickness of the steel reinforcement, h_s , shall satisfy:

- At the service limit state:

$$h_s \geq \frac{3h_{ri}\sigma_s}{F_y} \quad (14.7.5.3.5-1)$$

- At the fatigue limit state:

$$h_s \geq \frac{2h_{ri}\sigma_L}{\Delta F_{TH}} \quad (14.7.5.3.5-2)$$

where:

ΔF_{TH}	=	constant amplitude fatigue threshold for Category A as specified in Article 6.6 (ksi)
h_{ri}	=	thickness of i th internal elastomeric layer (in.)
σ_L	=	average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi)
σ_s	=	average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)
F_y	=	yield strength of steel reinforcement (ksi)

If holes exist in the reinforcement, the minimum thickness shall be increased by a factor equal to twice the gross width divided by the net width.

C14.7.5.3.5

The reinforcement should sustain the tensile stresses induced by compression of the bearing. With the present load limitations, the minimum steel plate thickness practical for fabrication will usually provide adequate strength.

Holes in the reinforcement cause stress concentrations. Their use should be discouraged. The required increase in steel thickness accounts for both the material removed and the stress concentrations around the hole.

14.7.5.3.6—Compressive Deflection

Deflections of elastomeric bearings due to dead load and to instantaneous live load alone shall be considered separately.

Loadings considered in this Article shall be at the service limit state with all load factors equal to 1.0.

Instantaneous live load deflection shall be taken as:

$$\delta_L = \sum \varepsilon_{Li} h_{ri} \quad (14.7.5.3.6-1)$$

where:

ε_{Li} = instantaneous live load compressive strain in i th elastomer layer

h_{ri} = thickness of i th elastomeric layer (in.)

Initial dead load deflection shall be taken as:

$$\delta_d = \sum \varepsilon_{di} h_{ri} \quad (14.7.5.3.6-2)$$

where:

ε_{di} = initial dead load compressive strain in i th elastomer layer

h_{ri} = thickness of i th elastomeric layer (in.)

Long-term dead load deflection, including the effects of creep, shall be taken as:

$$\delta_{lt} = \delta_d + a_{cr} \delta_d \quad (14.7.5.3.6-3)$$

where:

a_{cr} = creep deflection divided by initial dead load deflection

Values for ε_{Li} and ε_{di} shall be determined from test results or by analysis. Creep effects should be determined from information relevant to the elastomeric compound used. If the Engineer does not elect to obtain a value for the ratio, a_{cr} , from test results using Annex B of AASHTO M 251M/M 251, the values given in Table 14.7.6.2-1 may be used.

C14.7.5.3.6

Limiting instantaneous live load deflections is important to ensure that deck joints and seals are not damaged. Furthermore, bearings that are too flexible in compression could cause a small step in the road surface at a deck joint when traffic passes from one girder to the other, giving rise to additional impact loading. A maximum relative live load deflection across a joint of 0.125 in. is suggested. Joints and seals that are sensitive to relative deflections may require limits that are tighter.

Long-term dead load deflections should be considered where joints and seals between sections of the bridge rest on bearings of different design and when estimating redistribution of forces in continuous bridges caused by settlement.

Laminated elastomeric bearings have a nonlinear load-deflection curve in compression. In the absence of information specific to the particular elastomer to be used, Eq. C14.7.5.3.6-1 or Figure C14.7.6.3.3-1 may be used as an approximate guide for calculating dead and live load compressive strains for Eqs. 14.7.5.3.6-1 and 14.7.5.3.6-2. It should be noted that as shape factors become higher (greater than ≈ 6), the correlation of results between Eq. C14.7.5.3.6-1 and Figure C14.7.6.3.3-1 diverges. Eq. C14.7.5.3.6-1 provides a linear solution for a material that exhibits nonlinear behavior in compression. A bearing-specific value of axial strain may be found using Eqs. 14.7.5.3.3-15, C14.7.5.3.3-7 and C14.7.5.3.3-8.

$$\varepsilon = \frac{\sigma}{4.8GS^2} \quad (C14.7.5.3.6-1)$$

where:

σ = instantaneous live load compressive stress or dead load compressive stress in an individual elastomer layer (ksi)

S = shape factor of an individual elastomer layer

G = shear modulus of the elastomer (ksi)

Eq. C14.7.5.3.6-1 or Figure C14.7.6.3.3-1 may also be used as an approximate guide for specifying an allowable value of compressive strain at the design dead plus live service limit state compressive load when employing Section 8.8.1 of AASHTO M 251M/M 251.

Guidance for specifying an allowable value for creep when Annex B of AASHTO M 251M/M 251 is employed may be obtained from NCHRP Report 449 (Yura et al., 2001) or from Table 14.7.6.2-1.

Reliable test data on total deflections are rare because of the difficulties in defining the baseline for deflection. However, the change in deflection due to live load can be reliably predicted either by design aids based on test results or by using theoretically based equations (Stanton and Roeder, 1982). In the latter case, it is important to include the effects of bulk compressibility of the elastomer, especially for high shape factor bearings.

14.7.5.3.7—Seismic and Other Extreme Event Provisions

C14.7.5.3.7

Elastomeric expansion bearings shall be provided with adequate seismic and other extreme event resistant anchorage to resist the horizontal forces in excess of those accommodated by shear in the pad unless the bearing is intended to act as a fuse or irreparable damage is permitted. The sole plate and the base plate shall be made wider to accommodate the anchor bolts. Inserts through the elastomer should not be allowed, unless approved by the Engineer. The anchor bolts shall be designed for the combined effect of bending and shear for seismic and other extreme event loads as specified in Article 14.6.5.3. Elastomeric fixed bearings shall be provided with horizontal restraint adequate for the full horizontal load.

The seismic and other extreme event demands on elastomeric bearings exceed their design limits. Therefore, positive connection between the girder and the substructure concrete is needed. If the bearing is intended to act as a fuse or irreparable damage is permitted, the positive connection need not be designed for the maximum extreme event limit state forces.

Holes in elastomer cause stress concentrations that can lead to tearing of the elastomer during earthquakes.

14.7.5.4—Anchorage for Bearings without Bonded External Plates

In bearings without externally bonded steel plates, a restraint system shall be used to secure the bearing against horizontal movement if:

$$\frac{\theta_s}{n} \geq \frac{3\epsilon_a}{S_i} \quad (14.7.5.4-1)$$

where:

- n = number of interior layers of elastomer, where interior layers are defined as those layers which are bonded on each face. Exterior layers are defined as those layers which are bonded only on one face. When the thickness of the exterior layer of elastomer is equal to or greater than one-half the thickness of an interior layer, the parameter n may be increased by one-half for each such exterior layer.
- S_i = shape factor of the i th internal layer of an elastomeric bearing
- ϵ_a = total of static and cyclic average axial strain taken as positive for compression in which the cyclic component is multiplied by 1.75 from applicable service load combinations in Table 3.4.1-1 (ksi)
- θ_s = total of static and cyclic maximum service limit state design rotation angles of the elastomer specified in Article 14.4.2.1 in which the cyclic component is multiplied by 1.75 (rad.)

Military Specification MIL-C-882E, which can be found at <https://assist.dla.mil>. Note that there is no AASHTO equivalent to this Military Specification. A summary of testing and acceptance criteria for CDP is given below.

These criteria require that:

- A lot of preformed CDP be defined as a single sheet that is continuously formed to a given thickness except that a single lot not exceed 2,500 lbs of material;
- A minimum of two samples from each lot shall be tested;
- The samples be 2 in. × 2 in. with the full sheet thickness;
- The test specimens be cured for four hours at room temperature ($70^{\circ}\text{F} \pm 10^{\circ}\text{F}$);
- Each specimen is then to be loaded in compression, perpendicular to the direction of lamination;
- The origin of deflection and compressive strain measurements be taken at a compressive stress of 5 psi;
- The load be increased at a steady rate of 500 lbs/min. and the deflection be recorded;
- The specimen be loaded to a compressive stress of 10,000 psi without fracture or other failure; and
- The entire lot of CDP be rejected if any of the CDP specimens fail to satisfy either of these test criteria: The average compressive strain of the specimens for that lot is not to be less than 0.075 in./in. nor shall it be greater than 0.175 in./in. at an average compressive stress of 2,000 psi. Cotton-duck bearing pads which fail to achieve the 10,000 psi stress limit here fall outside the specified strain range and will not develop the deformation limits permitted in later parts of Article 14.7.

14.7.6.2—Material Properties

The elastomeric-type materials for PEP, FGP, and steel-reinforced elastomeric bearings shall satisfy the requirements of Article 14.7.5.2, except as noted below:

- Hardness on the Shore A scale may be used as a basis for specification of bearing material,
- The specified shear modulus for PEP, FGP, and steel-reinforced elastomeric bearings with a PTFE or equivalent slider on top of the bearing shall be between 0.080 ksi and 0.250 ksi or the nominal hardness shall be between 50 and 70 on the Shore A scale, and
- The specified shear modulus for steel-reinforced elastomeric bearings without a PTFE or equivalent slider on top of the bearing designed

C14.7.6.2

The elastomer requirements for PEP and FGP are the same as those required for steel-reinforced elastomeric bearings. The ranges given in Table 14.7.6.2-1 represent the variations found in practice. If the material is specified by hardness, a safe and presumably different estimate of G should be taken for each of the design calculations, depending on whether the parameter being calculated is conservatively estimated by over- or under-estimating the shear modulus. Creep varies from one compound to another and is generally more prevalent in harder elastomers or those with a higher shear modulus but is seldom a problem if high-quality materials are used. This is particularly true because the deflection limits are based on serviceability and are likely to be controlled by live load, rather than total load. The creep values given in

in accordance with the provisions of Article 14.7.6 shall be between 0.080 and 0.175 ksi or the nominal hardness shall be between 50 and 60 on the Shore A scale.

Table 14.7.6.2-1 are representative of neoprene and are conservative for natural rubber.

PEP, FGP, and steel-reinforced elastomeric bearings with or without a PTFE or equivalent slider on top of the bearing shall conform to the requirements of Article 18.2 of the *AASHTO LRFD Bridge Construction Specifications* and AASHTO M 251M/M 251. If the material is specified by its hardness, the shear modulus for design purposes shall be taken as the least favorable value from the range for that hardness given in Table 14.7.6.2-1. Intermediate values may be obtained by interpolation. If the material is specified by shear modulus, it shall be taken for design purposes as the least favorable from the value specified according to the ranges given in Article 14.7.5.2. Other properties, such as creep deflection, are also given in Table 14.7.6.2-1.

The shear force on the structure induced by deformation of the elastomer in PEP, FGP, and steel-reinforced elastomeric bearings shall be based on a G value not less than that of the elastomer at 73°F. Effects of relaxation shall be ignored.

CDP shall be manufactured to Military Specification MIL-C-882E except where the provisions of these Specifications supersede those provisions. The elastomeric-type materials for CDP shall have a nominal hardness between 50 and 70 on the Shore A scale and meet the requirements of Article 14.7.5.2 as appropriate. The finished CDP shall have a nominal hardness between 85 and 95 on the Shore A scale. The shear modulus for CDP may be estimated using Eq. 14.7.6.3.4-3. The cotton-duck reinforcement shall be either a two-ply cotton yarn or a single-ply 50-50 blend cotton-polyester. The fabric shall have a minimum tensile strength of 150 lb./in. width when tested by the grab method. The fill shall be 40 ± 2 threads per in., and the warp shall be 50 ± 1 threads per in. The CDP provisions included herein shall be taken as only applicable to bearing pads up to 2 in. in total thickness.

CDP is made of elastomers with hardness and properties similar to that used for PEP and FGP. However, the closely spaced layers of duck fabric reduce the indentation and increase the hardness of the finished pad to the 85 to 95 durometer range. Appendix X1 of AASHTO M 251M/M 251 contains provisions for hardness of elastomers, but not finished CDP. The acceptable range from the specified value for hardness of elastomers is ± 5 points on the Shore A scale. The acceptable range criteria for elastomers in AASHTO M 251M/M 251 may also be considered for finished CDP. The cotton-duck requirements are restated from the military specification because the reinforcement is essential to the good performance of these pads.

Table 14.7.6.2-1—Correlated Material Properties

	Hardness (Shore A)		
	50	60	70 ¹
Shear Modulus @ 73°F (ksi)	0.095–0.130	0.130–0.200	0.200–0.300
Creep deflection @ 25 yr divided by initial deflection	0.25	0.35	0.45

¹ Only for PEP, FGP, and steel-reinforced elastomeric bearings with a PTFE or equivalent slider on top of the bearing.

14.7.6.3—Design Requirements

14.7.6.3.1—Scope

Steel-reinforced elastomeric bearings may be designed in accordance with this Article, in which case they qualify for the test requirements appropriate for elastomeric pads. For this purpose, they shall be treated as FGP.

The provisions for FGP apply only to pads where the fiberglass is placed in double layers 0.125 in. apart.

The physical properties of neoprene and natural rubber used in these bearings shall conform to AASHTO M 251M/M 251.

14.7.6.3.2—Compressive Stress

At the service limit state, the average compressive stresses, σ_s and σ_L , in any layer shall satisfy:

- For PEP:
 $\sigma_s \leq 1.00GS$ and (14.7.6.3.2-1)
 $\sigma_s \leq 0.80 \text{ ksi}$ (14.7.6.3.2-2)
- For FGP:
 $\sigma_s \leq 1.25GS_i$ and (14.7.6.3.2-3)
 $\sigma_s \leq 1.0 \text{ ksi}$ (14.7.6.3.2-4)
- For CDP:
 $\sigma_s \leq 3.0 \text{ ksi}$ and (14.7.6.3.2-5)
 $\sigma_L \leq 2.0 \text{ ksi}$ (14.7.6.3.2-6)

where:

- σ_s = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)
 S = shape factor for PEP
 σ_L = average compressive stress at the service limit state (load factor = 1.0) due to live load (ksi)

In FGP, the value of S_i used shall be based upon an h_{ri} layer thickness which equals the greatest distance between midpoints of two double fiberglass reinforcement layers.

For steel-reinforced elastomeric bearings designed in accordance with the provisions of this Article:

C14.7.6.3.1

The design methods for elastomeric pads are simpler and more conservative than those for steel-reinforced bearings, so the test methods are less stringent than those of Article 14.7.5. Steel-reinforced elastomeric bearings may be made eligible for these less stringent testing procedures by limiting the compressive stress as specified in Article 14.7.6.3.2.

The three types of pad—PEP, FGP, and CDP—behave differently, so information relevant to the particular type of pad should be used for design. For example, in PEP, slip at the interface between the elastomer and the material on which it is seated or loaded is dependent on the friction coefficient, and this will be different for pads seated on concrete, steel, grout, epoxy, etc.

C14.7.6.3.2

In PEP, the compressive stress is limited to G times the shape factor and an absolute limit of 0.80 ksi. A stress check incorporating G times the shape factor limits the use of a proportionately thick PEP with a high compressive stress. In FGP, the compressive stress is limited to $1.25G$ times the effective shape factor and an absolute limit of 1.0 ksi. The CDP stress limits were developed to provide long-term serviceability and durability. CDP stiffness and behavior is less sensitive to shape factor. The total maximum compressive stress is limited to 3.0 ksi because experiments showed that CDP does not fail under monotonically compressive stress values significantly larger than this stress limit. CDP, which is subject to compressive stress levels larger than 3.0 ksi, may delaminate under dynamic loadings typical of those experienced by bridge bearings. CDP may experience dramatic failure when maximum compressive strains exceed approximately 0.25. However, bearing pads which meet the strain and stiffness limits which are required by the military specification will not achieve this failure strain under pure compressive load. The live load stresses are limited to 2.0 ksi because research shows that delamination is caused by the compressive stress range as well as the maximum compressive level. Live loads control the maximum compressive stress range under repeated loading, and this limit controls the adverse effects of this delamination. Larger compressive strains would result in increased damage to the bridge and the bearing pad and reduced serviceability of the CDP (Lehman et al., 2003).

The reduced stress limit for steel-reinforced elastomeric bearings designed in accordance with these provisions is invoked in order to allow these bearings to be eligible for the less stringent test requirements for elastomeric pads.

$$\sigma_s \leq 1.25GS_i \text{ and} \quad (14.7.6.3.2-7)$$

$$\sigma_s \leq 1.25 \text{ ksi} \quad (14.7.6.3.2-8)$$

where the value of S_i used shall be that of an internal layer of the bearing.

These stress limits may be increased by ten percent where shear deformation is prevented.

In FGP, the value of S_i used shall be based upon an h_{ri} layer thickness that equals the greatest distance between midpoints of two double fiberglass reinforcement layers.

14.7.6.3.3—Compressive Deflection

In addition to the provisions of Article 14.7.5.3.6, the following shall also apply.

In lieu of using specific product data, the compressive deflection of a FGP should be taken as 1.5 times the deflection estimated for steel-reinforced bearings of the same shape factor in Article 14.7.5.3.6.

The compressive deflection under instantaneous live load and initial dead load of a PEP or an internal layer of a steel-reinforced elastomeric bearing at the service limit state without impact shall not exceed $0.09h_{ri}$, where h_{ri} is the thickness of a PEP, or the thickness of an internal layer of a steel-reinforced elastomeric bearing (in.).

C14.7.6.3.3

The compressive deflection with PEP, FGP, and CDP will be larger and more variable than that of steel-reinforced elastomeric bearings. Appropriate data for these pad types may be used to estimate their deflections. In the absence of such data, the compressive deflection of a PEP and FGP may be estimated at 3 and 1.5 times, respectively, the deflection estimated for steel-reinforced bearings of the same shape factor in Article 14.7.5.3.6.

Figure C14.7.6.3.3-1 provides design aids for determining the strain in an elastomer layer for steel-reinforced bearings based upon durometer hardness and shape factor. It should also be noted that initial dead load compressive deflection does not include deflections associated with long-term creep.

Figure C14.7.6.3.3-1—Stress-strain Curves

For CDP, the computed compressive strain, ϵ_s , may be taken as:

$$\epsilon_s = \frac{\sigma_s}{E_c} \quad (14.7.6.3.3-1)$$

where:

- E_c = uniaxial compressive stiffness of the cotton-duck bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data (ksi)
- σ_s = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

CDP is typically very stiff in compression. The shape factor may be computed, but it has a different meaning and less significance to the compressive deflection than it does for FGP and PEP (Roeder et al., 2000). As a result, the maximum compressive deflection for CDPs can be based upon an average compressive strain, ϵ_s , for the total bearing pad thickness as computed in Eq. 14.7.6.3.3-1.

14.7.6.3.4—Shear

The maximum horizontal superstructure displacement shall be computed in accordance with Article 14.4. The maximum shear deformation of the pad at the service limit state, Δ_s , shall be taken as the maximum horizontal superstructure displacement, reduced to account for the pier flexibility and modified for construction procedures. If a low friction sliding surface is used, Δ_s need not be taken to be larger than the deformation corresponding to first slip.

The provisions of Article 14.7.5.3.2 shall apply, except that the pad shall be designed as follows:

- For PEP, FGP, and steel-reinforced elastomeric bearings:

$$h_{rt} \geq 2\Delta_s \quad (14.7.6.3.4-1)$$

- For CDP:

$$h_{rt} \geq 10\Delta_s \quad (14.7.6.3.4-2)$$

where:

h_{rt} = smaller of total elastomer or bearing thickness (in.)

Δ_s = maximum total shear deformation of the bearing from applicable service load combinations in Table 3.4.1-1 (in.)

The shear modulus, G , for CDP for determination of the bearing force in Article 14.6.3.1 may be conservatively estimated as:

$$G = 2\sigma_s \geq 2.0 \text{ ksi} \quad (14.7.6.3.4-3)$$

where:

σ_s = average compressive stress due to total load from applicable service load combinations in Table 3.4.1-1 (ksi)

14.7.6.3.5—Rotation

14.7.6.3.5a—General

The provisions of these Articles shall apply at the service limit state. Rotations shall be taken as the maximum sum of the effects of initial lack of parallelism and subsequent girder end rotation due to imposed loads and movements. Stress shall be the maximum stress associated with the load conditions inducing the maximum rotation.

C14.7.6.3.4

The deformation in PEP and FGP is limited to $\pm 0.5 h_{rt}$ because these movements are the maximum tolerable for repeated and long-term strains in the elastomer. These limits are intended to ensure serviceable bearings with no deterioration of performance and they limit the forces that the pad transmits to the structure.

In CDP, the shear deflection is limited to only one-tenth of the total elastomer thickness. There are several reasons for this limitation. First, experiments show that CDP may split and crack at larger shear strains. Second, CDP has much larger shear stiffness than that noted with steel-reinforced elastomeric bearings, PEP, and FGP, and so the strain limit assures that CDPs do not cause dramatically larger bearing forces to the structure than do other bearing systems. Third, the greater shear stiffness means that relative slip between the CDP and the bridge girders is likely if the deformation required of the bearing is too large. Slip may lead to abrasion and deterioration of the pads, as well as other serviceability concerns. Slip may also lead to increased costs because of anchorage and other requirements. Finally, CDPs are harder than PEPs and FGPs, and so they are very suitable for the addition of PTFE sliding surfaces to accommodate the required bridge movements. As a result, CDPs with large translational movements is invariably designed with PTFE sliding surfaces.

C14.7.6.3.5a

In the fourth edition of the Specifications, rotation of steel-reinforced elastomeric bearings and elastomeric pads was, in part, controlled by preventing uplift between the bearing and the structure. Research (Stanton et al., 2007) has shown that liftoff is not a concern for elastomeric bearings and the “no liftoff” provisions were removed from Method B as described in Article C14.7.5.3.3. Furthermore, as explained in Article C14.7.6.1, design for rotation in Method A is implicit in the geometric and stress limits given. Therefore, the “no liftoff” provisions have been removed from Method A in order to provide consistency between the two procedures.

14.7.6.3.5b—Rotation of CDP

The maximum compressive strain due to combined compression and rotation of CDP at the service limit state, ϵ_s , shall not exceed:

$$\epsilon_s = \epsilon_c + \frac{\theta_s L}{2t_p} < 0.20 \quad (14.7.6.3.5b-1)$$

where:

$$\epsilon_c = \frac{\sigma_s}{E_c} \quad (14.7.6.3.5b-2)$$

Maximum rotation shall be limited to:

$$\theta_s \leq 0.80 \frac{2t_p \epsilon_c}{L} \text{ and} \quad (14.7.6.3.5b-3)$$

$$\theta_L \leq 0.20 \frac{2t_p \epsilon_c}{L} \quad (14.7.6.3.5b-4)$$

where:

- E_c = uniaxial compressive stiffness of the cotton-duck bearing pad. It may be taken as 30 ksi in lieu of pad-specific test data
- L = length of a cotton-duck bearing pad in the plane of rotation (in.)
- t_p = total thickness of CDP (in.)
- ϵ_c = maximum uniaxial strain due to compression under total load from applicable service load combinations in Table 3.4.1-1
- ϵ_s = maximum uniaxial strain due to combined compression and rotation from applicable service load combinations in Table 3.4.1-1
- σ_s = average compressive stress due to total load associated with the maximum rotation from applicable service load combinations in Table 3.4.1-1 (ksi)
- θ_L = maximum rotation of the CDP at the service limit state (load factor = 1.0) due to live load (rad.)
- θ_s = maximum rotation of the CDP from the applicable service load combinations in Table 3.4.1-1 (rad.)

Additionally, it has been shown that the Method A limit on S_r^2/n (Article 14.7.6.1) prevents the build-up of any significant hydrostatic tension in bearings with bonded external plates.

C14.7.6.3.5b

Rotation, and combined compression and rotation of CDPs are controlled by shear strain limits and delamination requirements. Experiments show that CDP that meets the testing requirements of Military Specification MIL-C-882E will not fracture or fail until a combined compressive strain exceeds 0.25. Creep strains do not contribute to this fracture potential. Design Eq. 14.7.6.3.5b-1 limits this compressive strain to 0.20, because the design is made with service loads, and research shows that the 0.20 strain limit is sufficiently far from the average failure strain to assure a β factor of 3.5 for LRFD design. Delamination due to rotation is associated with uplift or separation between the bearing pad and the load surface. Delamination does not result in a fracture or immediate failure of the bearing pad, but it results in a significant reduction in the bearing service life. Cyclic rotation associated with live loads represents the more severe delamination problem, and Eq. 14.7.6.3.5b-4 provides this design limit. However, research also shows that delamination is also influenced by maximum rotation level. CDP do not recover all of their compressive deformation after unloading, and Eq. 14.7.6.3.5b-3 recognizes approximately 20 percent residual compressive strain and limits uplift due to the maximum rotation in recognition of the delamination potential. Shear strains of the elastomer are a less meaningful measure for CDP than for steel-reinforced elastomeric bearings, because shape factor has a different meaning for CDP than for other elastomeric bearing types. CDP is known to have relatively large compressive load capacity, and it is generally accepted that it can tolerate relatively large compressive strains associated with these loads. It should be noted that these compressive strains in CDPs are larger than those tolerated in steel-reinforced bearings, but they have been justified by experimental results for CDP that meets the requirements of these Specifications. This does not suggest that CDP is generally superior to steel-reinforced elastomeric bearings. A well designed steel-reinforced bearing is likely to provide superior long-term performance, but CDPs can be designed and manufactured quickly and may provide good performance under a range of conditions.

14.7.6.3.6—Stability

To ensure stability, the total thickness of the pad shall not exceed the least of $L/3$, $W/3$, or $D/4$.

where:

- L = plan dimension of the bearing perpendicular to the axis of rotation under consideration (generally parallel to the global longitudinal bridge axis) (in.)
- n = number of interior layers of elastomer, where interior layers are defined as those layers that are bonded on each face. Exterior layers are defined as those layers that are bonded only on one face. When the thickness of the exterior layer of elastomer is more than one-half the thickness of an interior layer, the parameter n may be increased by one-half for each such exterior layer.
- W = plan dimension of the bearing parallel to the axis of rotation under consideration (generally parallel to the global transverse bridge axis) (in.)
- D = diameter of pad (in.)

14.7.6.3.7—Reinforcement

The reinforcement in FGP shall be fiberglass with a strength in each plan direction of at least $2.2 h_{ri}$ in kip/in. For the purpose of this Article, if the layers of elastomer are of different thicknesses, h_{ri} shall be taken as the mean thickness of the two layers of the elastomer bonded to the same reinforcement. If the fiberglass reinforcement contains holes, its strength shall be increased over the minimum value specified herein by twice the gross width divided by net width.

Reinforcement for steel-reinforced elastomeric bearings designed in accordance with the provisions of this Article shall conform to the requirements of Article 14.7.5.3.5.

14.7.6.3.8—Seismic and Other Extreme Event Provisions

Expansion bearings designed according to Article 14.7.6 shall be provided with adequate seismic and other extreme event resistant anchorage to resist the horizontal forces in excess of those accommodated by shear in the pad unless the bearing is intended to act as a fuse or irreparable damage is permitted. The provisions of Article 14.7.5.3.7 shall also apply as applicable.

C14.7.6.3.6

The stability provisions in this Article are unlikely to have a significant impact upon the design of PEP, since a plain pad which has this geometry would have such a low allowable stress limit that the design would be uneconomical.

The buckling behavior of FGP and CDP is complicated because the mechanics of their behavior is not well understood. The reinforcement layers lack the stiffness of the reinforcement layers in steel-reinforced bearings and so stability theories developed for steel-reinforced bearings do not apply to CDP or FGP. The geometric limits included here are simple and conservative.

C14.7.6.3.7

The reinforcement should be strong enough to sustain the stresses induced in it when the bearing is loaded in compression. For a given compression, thicker elastomer layers lead to higher tension stresses in the reinforcement. It should be possible to relate the minimum reinforcement strength to the compressive stress that is allowed in the bearing in Article 14.7.6.3.2. The relationship has been quantified for FGP. For PEP and CDP, successful past experience is the only guide currently available.

For steel-reinforced elastomeric bearings designed in accordance with the provisions of Article 14.7.6, the equations from Article 14.7.5.3.5 are used. Although these equations are intended for steel-reinforced bearings with a higher allowable stress, the thickness of reinforcing sheets required is not significantly greater than those required by the old Method A.

14.7.7—Bronze or Copper-Alloy Sliding Surfaces

14.7.7.1—Materials

Bronze or copper alloy may be used for:

- flat sliding surfaces to accommodate translational movements,
- curved sliding surfaces to accommodate translation and limited rotation, and
- pins or cylinders for shaft bushings of rocker bearings or other bearings with large rotations.

Bronze sliding surfaces or castings shall conform to ASTM B22 and shall be made of Alloy C90500, C91100, or C86300 unless otherwise specified. The mating surface shall be structural steel, which has a Brinell hardness value at least 100 points greater than that of the bronze.

C14.7.7.1

Bronze or copper-alloy sliding surfaces have a long history of application in the United States with relatively satisfactory performance of the different materials. However, there is virtually no research to substantiate the properties and characteristics of these bearings. Successful past experience is the best guide currently available.

Historically these bearings have been built from sintered bronze, lubricated bronze, or copper alloy with no distinction between the performance of the different materials. However, the evidence suggests otherwise. Sintered bronze bridge bearings have historically been included in the Standard Specifications. Sintered bronze is manufactured with a metal powder technology, which results in a porous surface structure that is usually filled with a self-lubricating material. There do not appear to be many manufacturers of sintered bronze bridge bearings at this time, and there is some evidence that past bridge bearings of this type have not always performed well. As a result, there is no reference to sintered bronze herein.

Lubricated bronze bearings are produced by a number of manufacturers, and they have a relatively good history of performance. The lubrication is forced into a pattern of recesses, and the lubrication reduces the friction and prolongs the life of the bearing. Plain bronze or copper lacks this self-lubricating quality and would appear to have poorer bearing performance. Some jurisdictions use the following guidelines for lubricant recesses (FHWA, 1991):

- The bearing surfaces should have lubricant recesses consisting of either concentric rings, with or without central circular recesses with a depth at least equal to the width of the rings or recesses.
- The recesses or rings should be arranged in a geometric pattern so that adjacent rows overlap in the direction of motion.
- The entire area of all bearing surfaces that have provision for relative motion should be lubricated by means of the lubricant-filled recesses.
- The lubricant-filled areas should comprise not less than 25 percent of the total bearing surface.
- The lubricating compound should be integrally molded at high pressure and compressed into the rings or recesses and project not less than 0.010 in. above the surrounding bronze plate.

Bronze or copper-alloy sliding expansion bearings shall be evaluated for shear capacity and stability under lateral loads.

The mating surface shall be made of steel and be machined to match the geometry of the bronze surface so as to provide uniform bearing and contact.

14.7.7.2—Coefficient of Friction

The coefficient of friction may be determined by testing. In lieu of such test data, the design coefficient of friction may be taken as 0.1 for self-lubricating bronze components and 0.4 for other types.

14.7.7.3—Limit on Load

The nominal bearing stress due to combined dead and live load at the service limit state shall not exceed the values given in Table 14.7.7.3-1.

Table 14.7.7.3-1—Bearing Stress at the Service Limit State

ASTM B22 Bronze Alloy	Bearing Stress (ksi)
C90500—Type 1	2.0
C91100—Type 2	2.0
C86300—Type 3	8.0

14.7.7.4—Clearances and Mating Surfaces

The mating surface shall be steel that is accurately machined to match the geometry of the bronze surface and to provide uniform bearing and contact.

14.7.8—Disc Bearings

14.7.8.1—General

The dimensions of the elements of a disc bearing shall be such that hard contact between metal components, which prevents further displacement or rotation, will not occur under the least favorable combination of design displacements and rotations at the strength limit state.

Bronze or copper-alloy sliding expansion bearings should be evaluated for stability. The sliding plates inset into the metal of the pedestals or sole plates may lift during high horizontal loading. Guidelines for bearing stability evaluations may be found in Gilstad (1990). The shear capacity and stability may be increased by adding anchor bolts inserted through a wider sole plate and set in concrete.

The mating surface is commonly manufactured by a steel fabricator rather than by the bearing manufacturer who produces the bronze surface. This contractual arrangement is discouraged because it can lead to a poor fit between the two components. The bronze is weaker and softer than the steel, and fracture and excessive wear of the bronze may occur if there is inadequate quality control.

C14.7.7.2

The best available experimental evidence suggests that lubricated bronze can achieve a coefficient of friction on the order of 0.07 during its early life, while the lubricant projects above the bronze surface. The coefficient of friction is likely to increase to approximately 0.10 after the surface lubrication wears away and the bronze starts to wear down into the recessed lubricant. Copper alloy or plain bronze would cause considerably higher friction. In the absence of better information, conservative coefficients of friction of 0.1 and 0.4, respectively, are recommended for design.

C14.7.8.1

A disc bearing functions by deformation of a polyether urethane disc, which should be stiff enough to resist vertical loads without excessive deformation and yet be flexible enough to accommodate the imposed rotations without liftoff or excessive stress on other components,

The disc bearing shall be designed for the maximum strength limit state design rotation, θ_u , specified in Article 14.4.2.2.2.

For the purpose of establishing the forces and deformations imposed on a disc bearing, the axis of rotation may be taken as lying in the horizontal plane at midheight of the disc. The urethane disc shall be held in place by a positive location device.

Limiting rings may be used to partially confine the elastomer against lateral expansion. They may consist of steel rings welded to the upper and lower plates or a circular recess in each of those plates.

If a limiting ring is used, the depth of the ring should be at least $0.03D_d$, where D_d is the diameter of the disc element.

14.7.8.2—Materials

The elastomeric disc shall be made from a compound based on polyether urethane, using only virgin materials. The hardness shall be between 45 and 65 on the Shore D scale.

The metal components of the bearing shall be made from structural steel conforming to AASHTO M 270M/M 270 (ASTM A709/A709M), Grade 36, 50, or 50W or from stainless steel conforming to ASTM A240/A240 M.

14.7.8.3—Elastomeric Disc

The elastomeric disc shall be held in location by a positive locator device.

At the service limit state, the disc shall be designed so that:

- its instantaneous deflection under total load does not exceed ten percent of the thickness of the unstressed disc, and the additional deflection due to creep does not exceed eight percent of the thickness of the unstressed disc;
- the components of the bearing do not lift off each other at any location; and
- the average compressive stress on the disc does not exceed 5.0 ksi. If the outer surface of the disc is not vertical, the stress shall be computed using the smallest plan area of the disc.

such as PTFE. The urethane disc should be positively located to prevent its slipping out of place.

The primary concerns are that clearances should be maintained and that binding should be avoided even at extreme rotations. The vertical deflection, including creep, of the bearing should be taken into account.

θ_u may also be considered at the extreme event limit state.

The depth of the limiting ring should be at least $0.03D_d$ to prevent possible overriding by the urethane disc under extreme rotation conditions.

C14.7.8.2

AASHTO LRFD Bridge Construction Specifications, Article 18.3.2, provides material specifications for polyether urethane compounds.

Polyether urethane can be compounded to provide a wide range of hardnesses. The appropriate material properties must be selected as an integral part of the design process because the softest urethanes may require a limiting ring to prevent excessive compressive deflection, whereas the hardest ones may be too stiff and cause too high a resisting moment. Also, harder elastomers generally have higher ratios of creep to elastic deformation.

AASHTO M 270M/M 270 (ASTM A709/A709M), Grades 100 and 100W steel should be used only where their reduced ductility will not be detrimental.

C14.7.8.3

The primary concerns are that clearances should be maintained and that binding should be avoided even at extreme rotations. The vertical deflection, including creep, of the bearing should be taken into account.

Design of the urethane disc may be based on the assumption that it behaves as a linear elastic material, unrestrained laterally at its top and bottom surfaces. The estimates of resisting moments, so calculated, will be conservative, because they ignore creep, which reduces the moments. However, the compressive deflection due to creep should also be accounted for. Limiting rings stiffen the bearing. In compression, limiting rings make the bearing behave more like a confined elastomeric bearing, i.e., a pot bearing. Their influence is conservatively ignored in the linear elastic design approach. Subject to the approval of the Engineer, design methods based on test data are permitted.

No liftoff of components can be tolerated; therefore, any uplift restraint device should have sufficiently small vertical slack to ensure the correct location of all components when the compressive load is reapplied.

If a PTFE slider is used, the stresses on the PTFE slider shall not exceed the values for average and edge stresses given in Article 14.7.2.4 for the service limit state. The effect of moments induced by the urethane disc shall be included in the stress analysis.

14.7.8.4—Shear Resisting Mechanism

In fixed and guided bearings, a shear-resisting mechanism shall be provided to transmit horizontal forces between the upper and lower steel plates. It shall be capable of resisting a horizontal force in any direction equal to the larger of the design shear force at the strength and extreme event limit states or 15 percent of the design vertical load at the service limit state.

The horizontal design clearance between the upper and lower components of the shear-restricting mechanism shall not exceed the value for guide bars given in Article 14.7.9.

14.7.8.5—Steel Plates

The provisions of Sections 3, 4, and 6 of these Specifications shall apply as appropriate.

The thickness of each of the upper and lower steel plates shall not be less than $0.045 D_d$, where D_d is the diameter of the disc element, if it is in direct contact with a steel girder or distribution plate, or $0.06 D_d$ if it bears directly on grout or concrete.

14.7.9—Guides and Restraints

14.7.9.1—General

Guides may be used to prevent movement in one direction. Restraints may be used to permit only limited movement in one or more directions. Guides and restraints shall have a low-friction material at their sliding contact surfaces.

Rotational experiments have shown that uplift occurs at relatively small moments and rotations in disc bearings. There are concerns that this could lead to edge loading on PTFE sliding surfaces and increase the potential for damage to the PTFE. Bearings passing the test requirements of Article 18.3.4.4.4 of the AASHTO *LRFD Bridge Construction Specifications* should assure against any damage to the PTFE.

C14.7.8.4

The shear-resisting device may be placed either inside or outside the urethane disc. If shear is carried by a separate transfer device external to the bearing, such as opposing concrete blocks, the bearing itself may be unguided.

In unguided bearings, the shear force that should be transmitted through the body of the bearing is μP , where μ is the coefficient of friction of the PTFE slider and P is the vertical load on the bearing. This may be carried by the urethane disc without a separate shear-resisting device, provided that the disc is held in place by positive locating devices, such as recesses in the top and bottom plates.

The 15 percent factor applied to the service limit state vertical load approximates a strength limit state horizontal design force.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

C14.7.8.5

The plates should be thick enough to uniformly distribute the concentrated load in the bearing. Distribution plates should be designed in accordance with Article 14.8.

C14.7.9.1

Guides are frequently required to control the direction of movement of a bearing. If the horizontal force becomes too large to be carried reliably and economically on a guided bearing, a separate guide system may be used.

14.7.9.2—Design Loads

Guides or restraints shall be designed at the strength limit state for:

- the horizontal force from applicable strength load combinations specified in Table 3.4.1-1, but shall not be taken less than
- 15 percent of the total vertical force from applicable service load combinations specified in Table 3.4.1-1 acting on all the bearings at the bent divided by the number of guided bearings at the bent.

Guides and restraints shall be designed for applicable seismic or other extreme event forces using the extreme event limit state load combinations of Table 3.4.1-1 and, in the case of seismic, the provisions in Article 3.10.9.

14.7.9.3—Materials

For steel bearings, the guide or restraint shall be made from steel conforming to AASHTO M 270M/M 270 (ASTM A709/A709M), Grades 36, 50, or 50W or stainless steel conforming to ASTM A240/A240 M. For aluminum bearings, the guide may also be aluminum.

The low-friction interface material shall be approved by the Engineer.

14.7.9.4—Geometric Requirements

Guides shall be parallel, long enough to accommodate the full design displacement of the bearing in the sliding direction, and shall permit a minimum of 0.03125 in. and a maximum of 0.0625 in. free slip in the restrained direction. Guides shall be designed to avoid binding under all design loads and displacements, including rotation.

14.7.9.5—Design Basis**14.7.9.5.1—Load Location**

The horizontal force acting on the guide or restraint shall be assumed to act at the centroid of the low-friction interface material. Design of the connection between the guide or restraint and the body of the bearing system shall consider both shear and the overturning moments so caused.

C14.7.9.2

The 15 percent factor applied to the service limit state vertical load approximates a minimum strength limit state horizontal design force. This design force is intended to account for responses that cannot be calculated reliably, such as horizontal bending or twisting of a bridge deck caused by nonuniform or time-dependent thermal effects.

Large ratios of horizontal to vertical load can lead to bearing instability, in which case a separate guide system should be considered.

Maximum extreme event limit state forces should be considered when the bearing is not intended to act as a fuse or irreparable damage is not permitted.

C14.7.9.3

Many different low-friction materials have been used in the past. Because the total transverse force at a bent is usually smaller than the total vertical force, the guides may contribute less toward the total longitudinal friction force than the primary sliding surfaces. Thus, material may be used that is more robust but causes higher friction than the primary material. Filled PTFE is common, and other proprietary materials, such as PTFE-impregnated metals, have proven effective.

C14.7.9.4

Guides must be parallel to avoid binding and inducing longitudinal resistance. The clearances in the transverse direction are fairly tight and are intended to ensure that excessive slack does not exist in the system. Free transverse slip has the advantage that transverse restraint forces are not induced, but if this is the objective a nonguided bearing is preferable. On the other hand, if applied transverse loads are intended to be shared among several bearings, free slip causes the load to be distributed unevenly, possibly leading to overloading of one guide.

C14.7.9.5.1

Guides are often bolted to the slider plate to avoid welding distortions. Horizontal forces applied to the guide cause some overturning moment, which must be resisted by the bolts in addition to shear. The tension in the bolt can be reduced by using a wider guide bar. If high-strength bolts are used, the threaded hole in the plate should be deep enough to develop the full tensile strength of the bolt.

The design and detailing of bearing components resisting lateral loads, including seismic and other extreme event loads determined as specified in Article 14.6.3.1, shall provide adequate strength and ductility. Guide bars and keeper rings or nuts at the ends of pins and similar devices shall either be designed to resist all imposed loads or an alternative load path shall be provided that engages before the relative movement of the substructure and superstructure is excessive.

14.7.9.5.2—Contact Stress

The contact stress on the low-friction material shall not exceed that recommended by the manufacturer. For PTFE, the stresses at the service limit state shall not exceed those specified in Table 14.7.2.4-1 under sustained loading or 1.25 times those stresses for short-term loading.

14.7.9.6—Attachment of Low-Friction Material

The low-friction material shall be attached by at least any two of the following three methods:

- mechanical fastening,
- bonding, and
- mechanical interlocking with a metal substrate.

14.7.10—Other Bearing Systems

Bearing systems made from components not specified in Articles 14.7.1 through 14.7.9 may also be used, subject to the approval of the Engineer. Such bearings shall be adequate to resist the forces and deformations imposed on them at the service and strength limit states without material distress and without inducing deformations detrimental to their proper functioning. At the extreme event limit state, bearings which are designed to act as fuses or sustain irreparable damage may be permitted by the Owner, provided that loss of span is prevented.

The dimensions of the bearing shall be chosen to provide for adequate movements at all times. Materials shall have sufficient strength, stiffness, and resistance to

Some press-fit guide bar details in common use have proven unsatisfactory in resisting horizontal loads. When analyzing such designs, consideration should be given to the possibility of rolling the bar in the recess (SCEF, 1991).

Where guide bars are recessed into a machined slot, tolerances should be specified to provide a press fit. The guide bar should also be welded or bolted to resist overturning.

Past earthquakes have shown that guide and keeper bars and keeper rings or nuts at the ends of pins and other guiding devices have failed, even under moderate seismic loads. In an experimental investigation of the strength and deformation characteristics of rocker bearings (Mander et al., 1993), it was found that adequately sized pintles are sometimes capable of providing the necessary resistance to seismic loads.

C14.7.9.5.2

Appropriate compressive stresses for proprietary materials should be developed by the Manufacturer and approved by the Engineer on the basis of test evidence. Strength, cold flow, wear, and friction coefficient should be taken into consideration.

On conventional materials, higher stresses are allowed for short-term loading because the limitations in Table 14.7.2.4-1 are based partly on creep considerations. Short-term loading includes wind, earthquake, etc., but not thermal or gravity effects.

C14.7.9.6

Some difficulties have been experienced where PTFE is attached to the metal backing plates by bonding alone. Ultraviolet light attacks the PTFE surface that is etched prior to bonding, and this has caused bond failures. Thus, at least two separate methods of attachment are required. Mechanical fasteners should be countersunk to avoid gouging the mating surface.

C14.7.10

Tests cannot be prescribed unless the nature of the bearing is known. In appraising an alternative bearing system, the Engineer should plan the test program carefully because the tests constitute a larger part of the quality assurance program than is the case with more widely used bearings.

In bearings that rely on elastomeric components, aspects of behavior, such as time-dependent effects, response to cyclic loading, temperature sensitivity, etc., should be investigated.

Some bearing tests are very costly to perform. Other bearing tests cannot be performed because there is no available test equipment in the United States. At the

creep and decay to ensure the proper functioning of the bearing throughout the design life of the bridge.

The Engineer shall determine the tests that the bearing shall satisfy. The tests shall be designed to demonstrate any potential weakness in the system under individual compressive, shear, or rotational loading or combinations thereof. Testing under sustained and cyclic loading shall be required.

present time, the largest U.S. facility for testing bearings in combined axial load and shear is the Seismic Response Modification Device Test Facility at the University of California, San Diego constructed by Caltrans. This facility can test bearings of all kinds up to 12,000-kip axial load capacity and 2,000-kip transverse load capacity (HITEC, 2002). Nevertheless, the following test requirements should be carefully considered before specifying them (SCEF, 1991):

- Vertical loads exceeding 5,000 kips,
- Horizontal loads exceeding 500 kips,
- The simultaneous application of horizontal and vertical load where the horizontal load exceeds 75 percent of the vertical load,
- Triaxial test loading,
- The requirement for dynamic rotation of the test bearing while under vertical load, and
- Coefficient of friction test movements with normal loads greater than 250 kips.

14.8—LOAD PLATES AND ANCHORAGE FOR BEARINGS

14.8.1—Plates for Load Distribution

The bearing, together with any additional plates, shall be designed so that:

- The combined system is stiff enough to prevent distortions of the bearing that would impair its proper functioning when subjected to service and strength limit state loadings, and maximum extreme event loadings when required;
- The stresses imposed on the supporting structure satisfy the limits specified by the Engineer and Sections 5, 6, 7, or 8; and
- The bearing can be replaced within the jacking height limits specified by the Engineer without damage to the bearing, distribution plates, or supporting structure. If no limit is given, a height of 0.375 in. shall be used.

Resistance of steel components shall be determined in accordance with Section 6.

In lieu of a more refined analysis, the load from a bearing fully supported by a grout bed may be assumed to distribute at a slope of 1.5:1, horizontal to vertical, from the edge of the smallest element of the bearing that resists the compressive load.

The use and design of bearing stiffeners on steel girders shall comply with Section 6.

Sole plate and base plate connections shall be adequate to resist lateral loads at the strength limit state. These connections shall also be adequate to resist the

C14.8.1

Large forces may be concentrated in a bearing that must be distributed so as not to damage the supporting structure. In general, metal rocker and roller bearings cause the most concentrated loads, followed by pots, discs, and sphericals, whereas elastomeric bearings cause the least concentrated loads. Masonry plates may be required to prevent damage to concrete or grout surfaces.

Many simplified methods have been used to design masonry plates, some based on strength and some on stiffness. Several studies have indicated that masonry plates are less effective in distributing the load than these simplified methods would suggest, but the cost of heavy load distribution plates would be considerable (McEwen and Spencer, 1981; Saxena and McEwen, 1986). The present design rules represent an attempt to provide a uniform basis for design that lies within the range of traditional methods. Design based on more precise information, such as finite element analysis, is preferable but may not be practical in many cases.

One common way to provide for replacement is to use a masonry plate attached to the concrete pier head by embedded anchors or anchor bolts. The bearing can then be attached to the masonry plate by seating it in a machined recess and bolting it down. The bridge needs then to be lifted only through a height equal to the depth of the recess in order to replace the bearing. The deformation tolerance of joints and seals, as well as the stresses in the structure, should be considered in determining the allowable jacking height.

maximum seismic and other extreme event lateral loads unless the bearings are designed to act as fuses or sustain irreparable damage. Sole plates shall be extended to allow for anchor bolt inserts when required.

14.8.2—Tapered Plates

If, under full permanent load at the mean annual temperature for the bridge site (at the service limit state with all load factors equal to 1.0), the inclination of the underside of the girder to the horizontal exceeds 0.01 rad., a tapered plate shall be used in order to provide a level surface.

14.8.3—Anchorage and Anchor Bolts

14.8.3.1—General

All load distribution plates and bearings with external steel plates shall be positively secured to their associated superstructure or substructure element by bolting or welding.

All girders shall be positively secured to supporting bearings by a connection that can resist the horizontal forces that may be imposed on it unless fusing or irreparable damage is permitted at the extreme event limit state. Separation of bearing components shall not be permitted at the strength limit state. Connections shall resist the least favorable combination of loads at the strength limit state and shall be installed wherever deemed necessary to prevent separation.

Trusses, girders, and rolled beams shall be securely anchored to the substructure. Where possible, anchor bolts should be cast in substructure concrete, otherwise anchor bolts may be grouted in place. Anchor bolts may be swedged or threaded to secure a satisfactory grip upon the material used to embed them in the holes.

The resistance of the anchor bolts shall be adequate for loads at the strength limit state and for the maximum loads at the extreme event limit state unless the bearings are designed to act as fuses or sustain irreparable damage.

The tensile resistance of anchor bolts shall be determined as specified in Article 6.13.2.10.2.

C14.8.2

Tapered plates may be used to counteract the effects of end slope in a girder. In all but short-span bridges, the dead load will dominate the forces on the bearing, so the tapered plate should be designed to provide zero rotation of the girder under this condition. The limit of 0.01 rad. out of level corresponds to the 0.01 rad. component, which is required in the design rotation in Article 14.4.

C14.8.3.1

Bearings should be anchored securely to the support to prevent their moving out of place during construction or over the life of the bridge. Elastomeric bearings may be left without anchorage if adequate friction is available. A design coefficient of friction of 0.2 may be assumed between elastomer and clean concrete or steel.

Girders may be located on bearings by bolts or pintles. The latter provide no uplift capacity. Welding may be used, provided that it does not cause damage to the bearing or difficulties with replacement.

Uplift should be prevented both among the major elements, such as the girder, bearing, and support, and between the individual components of a bearing. If uplift occurs, some parts of the structure could be misaligned when contact is regained, causing damage.

Anchor bolts are very susceptible to brittle failure during earthquakes or other extreme events. To increase ductility, it has been recommended in Astaneh-Asl et al. (1994) to use upset anchor bolts placed inside hollow sleeve pipes and oversized holes in the masonry plate. Thus, deformable bearing types may use the anchor bolts as the ductile element (Cook and Klingner, 1992).

Bearings designed for rigid load transfer, especially at the extreme event limit state, should not be seated on grout pads or other bedding materials that can create a sliding surface and reduce the horizontal resistance.

Seismic loading of the anchor bolts has often resulted in concrete damage, especially when they were too close to the edge of the bearing seat. Guidelines for evaluating edge distance effects and concrete strength requirements may be found in Ueda et al. (1990), among others.

The shear resistance of anchor bolts and dowels shall be determined as specified in Article 6.13.2.12.

The resistance of anchor bolts in combined tension and shear shall be determined as specified in Article 6.13.2.11.

The bearing resistance of the concrete shall be taken as specified in Article 5.6.5. The modification factor, m , shall be based on a nonuniformly distributed bearing stress.

Anchors in concrete shall meet the requirements in Article 5.13.

14.8.3.2—Seismic and Other Extreme Event Design and Detailing Requirements

Sufficient reinforcement shall be provided around the anchor bolts to develop the level of horizontal forces considered at the extreme event limit state and anchor them into the mass of the substructure unit. Potential concrete crack surfaces next to the bearing anchorage shall be identified and their shear friction capacity evaluated as required.

14.9—CORROSION PROTECTION

All exposed steel parts of bearings not made from stainless steel shall be protected against corrosion by zinc metallization, hot-dip galvanizing, or a paint system approved by the Engineer. A combination of zinc metallization or hot-dip galvanizing and a paint system may be used.

As an approximation, the bearing stress may be assumed to vary linearly from zero at the end of the embedded length to its maximum value at the top surface of concrete.

C14.9

The use of stainless steel is the most reliable protection against corrosion because coatings of any sort are subject to damage by wear or mechanical impact. This is particularly important in bearings where metal-to-metal contact is inevitable, such as rocker and roller bearings. Weathering steel is excluded because it forms an oxide coating that may inhibit the proper functioning of the bearing.

When using hot-dip galvanizing for corrosion protection, several factors must be considered. Embrittlement of very high-strength fasteners, such as ASTM F3125, Grade A490 bolts, may occur due to acid cleaning (pickling) before galvanizing, and quenched and tempered material, such as Grade 70W and 100W, may undergo changes in mechanical properties, so galvanizing these should be avoided (see ASTM A143/A143M on avoiding embrittlement). With good practice, commonly used steels, such as Grades 36, 50, and 50W, should not be adversely affected if their chemistry and the assembly's details are compatible (see ASTM A385/A385M on ensuring high-quality coating). Certain types of bearings, such as intricate pot or spherical bearings, are not suitable for hot-dip galvanizing.

SECTION 15

DESIGN OF SOUND BARRIERS

Commentary is opposite the text it annotates.

15.1—SCOPE

This Section applies to the structural design of sound barriers which are either ground-mounted or structure-mounted and the design of the foundations of ground-mounted sound barriers.

C15.1

This Section specifies the design forces and the design requirements unique to sound barriers constructed along highways. This Section does not cover sound barriers constructed adjacent to railroad tracks or the acoustical requirements for sound barriers.

These provisions are largely based on the requirements of the *Guide Specifications for Structural Design of Sound Barriers* (1989).

15.2—DEFINITIONS

Clear Zone—The total roadside border area, starting at the edge of the traveled way, available for safe use by errant vehicles.

Crashworthy—A traffic railing system that has been successfully crash-tested to a currently acceptable crash test matrix and test level or one that can be geometrically and structurally evaluated as equal to a crash-tested system.

Ground-Mounted Sound Barriers—Sound barriers supported on shallow or deep foundations.

Post-and-Panel Construction—Type of sound barrier construction consisting of vertical posts supported on a structure or on the foundations and panels spanning horizontally between adjacent posts.

Right-of-Way—The land on which a roadway and its associated facilities and appurtenances are located. The highway right-of-way is owned and maintained by the agency having jurisdiction over that specific roadway.

Right-of-Way Line—The boundary of the right-of-way.

Sound Barrier—A wall constructed along a highway to lower the highway noise level in the area behind the wall.

Sound Barrier Setback—The distance between the point on the traffic face of the sound barrier wall that is closest to traffic and the closest point on the traffic face of the traffic railing the sound barrier is mounted on or located behind as defined in Article 15.8.4.

Structure-Mounted Sound Barriers—Sound barriers supported on bridges, crashworthy traffic railings, or retaining walls.

Traffic Railing—Synonymous with vehicular railing; used as a bridge- or structure-mounted railing rather than as a guardrail or median barrier, as in other publications.

Vehicular Railing—Synonymous with traffic railing; used as a bridge- or structure-mounted railing rather than as a guardrail or median barrier, as in other publications.

15.3—NOTATION

- S = setback distance of sound barrier (15.8.4)
 ϕ = soil angle of internal friction (degrees) (C15.4.2)
 γ_p = load factor for permanent loads (15.9.9)

15.4—GENERAL FEATURES

15.4.1—Functional Requirements

15.4.1.1—General

Consult a roadway professional for sight-distance and sound barrier height and length requirements.

15.4.1.2—Lateral Clearance

Unless dictated by site conditions and approved by the Owner, sound barriers shall be located outside the clear zone or, when the clear zone is wider than the distance between the edge of the traffic lanes and the edge of the available right-of-way, just inside the right-of-way.

C15.4.1.2

Locating the sound barrier farther from the edge of the traffic lanes reduces the possibility of vehicular collision with the barrier. The most desirable location for a sound barrier is outside the clear zone, which minimizes the possibility of vehicular collision. In many cases, because sound barriers are typically used in urban areas, the width of available right-of-way is less than the width of the clear zone.

When conditions make it impractical to locate the sound barrier at adequate distance from the edge of traffic lanes and the sound barrier is mounted on a traffic barrier, the recommended minimum clearance from the edge of traffic lanes to the face of the traffic barrier is 10.0 ft. Lateral clearances greater than 10.0 ft should be used when feasible. Guardrail or other traffic barriers should be considered for use when the sound barrier is located inside the clear zone.

In addition to safety considerations, maintenance requirements should be considered in deciding sound barrier locations. Sound barriers placed within the area between the shoulder and right-of-way line complicate the ongoing maintenance and landscaping operations and lead to increased costs, especially if landscaping is placed on both sides of the sound barrier. Special consideration should be given to maintaining the adjoining land behind the sound barrier and adjacent to the right-of-way line.

15.4.2—Drainage

Adequate drainage shall be provided along sound barriers.

C15.4.2

It is important to have drainage facilities along sound barriers to ensure soil stability. Soils with an angle of internal friction, ϕ , of 25 degrees or less may develop flowing characteristics when saturated. Limits on fines, especially clay and peat, should be specified.

15.4.3—Emergency Responder and Maintenance Access

Provisions for emergency and maintenance access shall be provided. Local fire department requirements for fire hose and emergency access shall be satisfied.

C15.4.3

Provisions may be necessary to allow firefighters and hazardous material clean-up crews access to fire hydrants on the opposite side of the sound barrier. The designer should consult with local fire and emergency officials regarding their specific needs.

Shorter barriers may be traversed by throwing the fire hose over the wall. Taller barriers may require an opening through which the hose is passed. Such an opening can consist of a formed or cored hole, a hollow masonry block turned on its side, a maintenance access

gate, etc. A small sign may be placed adjacent to the emergency access location on the traffic side of the sound barrier. This sign would bear the street name on which the hydrant is located, thus aiding emergency crews in identifying the hydrant nearest the opening.

Access to the back side of the sound barrier must be provided if the area is to be maintained. In subdivision areas, access can be via local streets, when available. If access is not available via local streets, access gates or openings are essential at intervals along the sound barrier. Offset barriers concealing the access opening must be overlapped a minimum of 2.5 times the offset distance in order to maintain the integrity of the main barrier's sound attenuation. Location of the access openings should be coordinated with the appropriate agency or land owner.

15.4.4—Differential Settlement of Foundations

For long masonry sound barriers supported on spread footings, provisions should be made to accommodate differential settlement.

15.5—LIMIT STATES AND RESISTANCE FACTORS

15.5.1—General

Structural components shall be proportioned to satisfy the requirements at all appropriate service, strength, and extreme event limit states.

Limit states applicable to sound barrier foundation design shall be in accordance with Article 15.9. Limit states applicable to the structural design of sound barrier components shall be as presented herein.

The limit states shall apply using the applicable load combinations in Table 3.4.1-1 and the loads specified herein.

Where masonry or other proprietary walls are utilized, the Owner shall approve the design specifications to be used.

15.5.2—Service Limit State

The resistance factors for the service limit states for post, wall panel, and foundation components shall be as specified in Article 1.3.2.1. Design for service limit states shall be in accordance with the applicable requirements of Articles 5.5.2, 6.5.2, 7.5.1, and 8.5.1.

15.5.3—Strength Limit State

The resistance factors for the strength limit states for post, wall panel, and foundation components shall be as specified in Articles 5.5.4, 6.5.4, 7.5.4, and 8.5.2.

C15.4.4

Provisions should be made to accommodate differential settlement when sound barriers are supported on continuous spread or trench footings or cap beams.

C15.5.1

These Specifications do not include design provisions for masonry structures. Design provisions for masonry structures should be taken from other specifications.

15.5.4—Extreme Event Limit State

The resistance factors for the extreme event limit states for post, wall panel, and foundation components shall be as specified in Article 1.3.2.1.

15.6—EXPANSION DEVICES

15.6.1—General

Adequate noise sealant material shall be placed at expansion joints of sound barriers.

15.6.2—Structure-Mounted Sound Barriers

Except for post-and-panel construction, as a minimum, expansion joints shall be provided in the sound barriers at the location of expansion joints in the supporting structure, at bridge intermediate supports, and at the centerline of bridge spans.

When post-and-panel construction is utilized, wall panels may be allowed to bridge the expansion joints in, or at the ends of, the deck of the supporting structure where the panels' seat width on the posts is sufficient to accommodate the expansion joint movements and the dimensional and installation tolerances; otherwise, posts shall be placed on either side of any expansion joint in the supporting structure.

15.6.3—Ground-Mounted Sound Barriers

Except for post-and-panel construction, expansion devices shall be provided at adequate spacing to allow for thermal expansion of the sound barriers. For sound

C15.6.2

When the type of construction utilized for sound barriers does not inherently allow movements between the sound barrier components, allowance should be made to accommodate the movement and deformations of the supporting structure. Therefore, expansion devices are required in the sound barriers at expansion joint locations in order not to restrict the movement of the expansion joints of the supporting structures.

Sound barriers mounted on bridges stiffen the supporting bridge superstructures, resulting in longitudinal stresses developing in the sound barriers. The higher curvature of bridge girders at high moment locations near midspans and, for continuous bridges, at intermediate supports increases the magnitude of these stresses. Providing expansion joints in the sound barriers at these locations reduces the effect of the stiffness of the sound barrier on the deformations of the girders and the stresses in the barrier due to live load deflection of the bridge.

When mounted on bridges, additional expansion devices in the sound barrier may be utilized as required to further minimize the stresses on the barrier due to the live load deflection of the bridge.

Post-and-panel sound barriers inherently provide an expansion joint at either end of each wall panel. Typical posts are made of steel rolled I-shapes or concrete I-sections. Characteristically, the seat width of the wall panels on the posts is relatively small as it corresponds to the width of the post flange overhang on either side of the post web. These typical seat widths provide for dimensional and installation tolerances and dimensional changes caused by panel deformations due to applied loads and temperature changes. For smaller post flange widths, unless a post is provided on either side of an expansion joint in the supporting structure, the change in the opening of the structure expansion joint may be larger than the panel seat width on the post and may cause the failure of the panel straddling the structure expansion joint due to the loss of panel seat width.

C15.6.3

For sound barriers not utilizing post-and-panel construction, minimizing the relative deflection between the wall sections on either side of an expansion joint

barriers prone to vehicular collision, relative deflection between the sound barriers on either side of an expansion joint shall be restricted.

improves the performance of the barrier during vehicular collision near the expansion joint. This can be accomplished by installing a sliding dowel-and-sleeve connection, similar to the one shown in Figure C15.6.3-1, near the top of the wall.

Figure C15.6.3-1—Sliding Dowel-and-Sleeve Connection

15.7—SOUND BARRIERS INSTALLED ON EXISTING BRIDGES

When sound barriers are installed on existing bridges, the effects of the sound barrier forces on existing bridge components shall be investigated, including the effect of unbalanced mass.

C15.7

Sound barrier forces transmitted to the bridge include the weight of the barrier, wind loads, seismic loads, vehicular collision forces, and any other forces that may act on the sound barriers. These forces affect railings, bridge deck overhangs, floorbeams, and girders.

When sound barriers are added on an existing bridge, the bridge should be reanalyzed to determine its load rating taking into account the forces applied to the sound barriers. The stiffening effect of the sound barriers may be considered when determining the load rating of the bridge.

15.8—LOADS

15.8.1—General

Unless explicitly modified below, all applicable loads shall be applied in accordance with the provisions of Section 3.

15.8.2—Wind Load

The provisions of Article 3.8.1 shall apply.

C15.8.2

The wind load provisions included in Article 3.8.1 are applicable to all structures, including sound barriers. This deviates from earlier specifications where special wind provisions for sound barriers were included.

15.8.3—Earth Load

The provisions of Article 3.11 shall apply.

C15.8.3

Article 3.11.5.10 contains specific requirements for the determination of earth pressure on sound barrier foundation components.

The possibility of difference between the actual finished grade and that shown on the contract documents should be considered in the design.

15.8.4—Vehicular Collision Forces

Sound barrier systems consisting of a traffic railing and a sound barrier that have been successfully crash-tested may be used with no further analysis.

The depth of aesthetic treatments into the traffic face of sound barrier that may be subjected to vehicular collision shall be kept to a minimum.

Sound barrier materials shall be selected to limit shattering of the sound barrier during vehicular collision.

In lieu of crash-testing, the resistance of components and connections to Extreme Event II force effects may be determined based on a controlled failure scenario with a load path and sacrificial elements selected to ensure desirable performance of a structural system containing the soundwall. Vehicular collision forces shall be applied to sound barriers located within the clear zone as follows:

Case 1: For sound barriers on a crashworthy traffic railing and for sound barriers mounted behind a crashworthy traffic railing with a sound barrier setback no more than 1.0 ft: vehicular collision forces specified in Section 13 shall be applied to the sound barrier at a point 4.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 3 and lower and 6.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 4 and higher.

Case 2: For sound barriers behind a crashworthy traffic railing with a sound barrier setback of 4.0 ft: vehicular collision force of 4.0 kips shall be applied. The collision force shall be assumed to act at a point 4.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 3 and lower and 14.0 ft above the surface of the pavement in front of the traffic railing for Test Levels 4 and higher.

Soil build-up against sound barriers has been observed in some locations. Owners may determine the earth loads for the worst load case assuming an allowance in the finished grade elevation.

C15.8.4

Minimizing the depth of aesthetic treatment into the traffic face of sound barriers that may be in contact with a vehicle during a collision reduces the possibility of vehicle snagging.

Sound barrier systems may contain sacrificial components or components that could need repair after vehicular collision. Limiting shattering of sound barriers is particularly important for sound barriers mounted on bridges crossing over other traffic. When reinforced concrete panels are utilized for structure-mounted sound barriers, it is recommended that two mats of reinforcement are used to reduce the possibility of the concrete shattering during vehicular collision. Restraint cables placed in the middle of concrete panels may be used to reduce shattering while avoiding the increased panel thickness required to accommodate two layers of reinforcement.

The bridge overhang or moment slabs need not be designed for more force effects than the resistance of the base connection of the sound barrier.

The design strategy involving a controlled failure scenario is similar in concept to the use of capacity protected design to resist seismic forces. Some damage to the soundwall, traffic barrier, or connections is often preferable to designing an overhang or moment slab for force effects due to vehicular collision. The bridge overhang or moment slabs need not be designed for more force effects than the resistance of the base connection of the sound barriers.

Some guidance on desirable structural performance of sound barriers can be found in European Standard EN1794-2 (2003).

Very limited information is available on crash-testing of sound barrier systems. The requirements of this Article, including the magnitude of collision forces, are mostly based on engineering judgment and observations made during crash-testing of traffic railings without sound barriers.

In the absence of crash test results for sound barrier systems, sound barriers that have not been crash-tested are often used in conjunction with vehicular railings that have been crash-tested as stand-alone railings, i.e. without sound barriers. The collision forces specified herein are meant to be applied to the sound barrier portion of such systems.

Crash Test Levels 3 and lower are performed using small automobiles and pick-up trucks. Crash Test Levels 4 and higher include single-unit, tractor-trailer trucks, or

Case 3: For sound barriers behind a crashworthy traffic railing with a sound barrier setback between 1.0 ft and 4.0 ft: vehicular collision forces and the point of application of the force shall vary linearly between their values and locations specified in Case 1 and Case 2 above.

Case 4: For sound barriers behind a crashworthy traffic railing with a sound barrier setback more than 4.0 ft; vehicular collision forces need not be considered.

both. The difference in height of the two groups of vehicles is the reason the location of the collision force is different at different Test Levels.

For crash Test Levels 3 and lower, the point of application of the collision force on the sound barriers is assumed to be always 4.0 ft above the pavement.

During crash-testing of traffic railings for crash Test Level 4 and higher, trucks tend to tilt above the top of the railing and the top of the truck cargo box may reach approximately 4.0 ft behind the traffic face of the traffic railing. For such systems, the point of application of the collision force is expected to be as high as the height of the cargo box of a truck, assumed to be 14.0 ft above the pavement surface.

For sound barriers mounted on crashworthy traffic barriers or with a small setback assumed to be less than 1.0 ft, the full crash force is expected to act on the sound barrier. The point of application of this force is assumed to be at the level of the cargo bed, taken as 6.0 ft above the surface of the pavement.

For a sound barrier mounted with a setback more than 1.0 ft behind the traffic face of the traffic railing, it is expected that the truck cargo box, not the cargo bed, will impact the sound barrier. It is expected that the top of the cargo box will touch the sound barrier first. Due to the soft construction of cargo boxes, it is assumed that they will be crushed and will soften the collision with the sound barrier. The depth of the crushed area will increase with the increase of the collision force, thus lowering the location of the resultant of the collision force. The magnitude of the collision force and the degree to which the cargo box is crushed are expected to decrease as the setback of the sound barrier increases.

In the absence of test results, it is assumed that a collision force of 4.0 kips will develop at the top of the cargo box when it impacts sound barriers mounted with a setback of 4.0 ft.

The collision force and the point of application are assumed to vary linearly as the sound barrier setback varies between 1.0 ft and 4.0 ft.

The setback of the sound barrier, S , shall be taken as shown in Figure 15.8.4-1.

Figure 15.8.4-1—Sound Barrier Setback Distance

Collision forces on sound barriers shall be applied as a line load with a length equal to the longitudinal length of distribution of collision forces, L_t , specified in Appendix A13.

For sound barriers prone to vehicular collision forces, the wall panels and posts and the post connections to the supporting traffic barriers or footings shall be designed to resist the vehicular collision forces at the Extreme Event II limit state.

For post-and-panel construction, the design collision force for the wall panels shall be the full specified collision force placed on one panel between two posts at the location that maximizes the load effect being checked. For posts and post connections to the supporting components, the design collision force shall be the full specified collision force applied at the point of application specified earlier in Cases 1 through 3.

The vehicular railing part of the sound barrier/railing system does not need to satisfy any additional requirements beyond the requirements specified in Section 13 of these Specifications for the stand-alone railings, including the height and resistance requirements.

Unless otherwise specified by the Owner, vehicular collision forces shall be considered in the design of sound barriers.

In some cases, the wall panel is divided into a series of horizontal elements. In these situations, each horizontal strip should be designed for the full design force.

Owners may elect to ignore vehicular collision forces in the design of sound barriers at locations where the collapse of the sound barrier or portions of thereof has minimal safety consequences.

15.9—FOUNDATION DESIGN

15.9.1—General

Unless otherwise specified by the Owner, the geotechnical resistance of materials supporting sound barrier foundations shall be estimated using the procedures presented in Article 10.6 for spread footings, Article 10.7 for driven piles, and Article 10.8 for drilled shafts.

C15.9.1

Although sound barriers may be supported on spread footing or driven pile foundations, drilled shafts are more commonly used because drilled shafts facilitate controlling the vertical alignment of sound barrier structural wall supports and the lateral spacing between them.

15.9.2—Determination of Soil and Rock Properties

The provisions of Articles 2.4 and 10.4 shall apply.

15.9.3—Limit States

Sound barriers shall be designed to withstand lateral wind and earth pressures, self-weight of the wall, vehicular collision loads, and earthquake loads in accordance with the general principles specified in this Section and in Sections 10 and 11.

Sound barriers shall be investigated for vertical and lateral displacement at the Service I Limit State. Tolerable deformation criteria shall be developed based on maintaining the required barrier functionality, achieving the anticipated service life, and the consequences of unacceptable movements.

Sound barrier foundations shall be investigated at the strength limit states using Eq. 1.3.2.1-1 for:

- Bearing-resistance failure,
- Overall stability, and
- Structural failure.

Sound barrier foundations shall be investigated at the extreme event limit states using the applicable load combinations and load factors specified in Table 3.4.1-1.

15.9.4—Resistance Requirements

The factored resistance, R_R , calculated for each applicable limit state shall be the nominal resistance, R_n , multiplied by an appropriate resistance factor, ϕ , specified in Articles 10.5.5.1, 10.5.5.2, 10.5.5.3, 11.5.6, or 11.5.7.

15.9.5—Resistance Factors

The resistance factors for geotechnical design of foundations shall be as specified in Table 10.5.5.2.2-1 for spread footing foundations, Table 10.5.5.2.3-1 for driven pile foundations, Table 10.5.5.2.4-1 for drilled shaft foundations, and Table 11.5.7-1 for permanent retaining walls.

If methods other than those prescribed in these Specifications are used to estimate geotechnical resistance, the resistance factors chosen shall provide reliability equal or greater than those given in Tables 10.5.5.2.2-1, 10.5.5.2.3-1, 10.5.5.2.4-1, and 11.5.7-1.

C15.9.4

Procedures for calculating nominal geotechnical resistance of footings, driven piles, and drilled shafts are provided in Articles 10.6, 10.7, and 10.8. These methods are generally accepted for barriers supported on spread footings or footings on two or more rows of driven piles or drilled shafts. The nominal geotechnical resistance of a single row of driven piles or drilled shafts or by a continuous embedded foundation wall (commonly referred to as a “trench footing”) is more appropriately calculated using the provisions in Article 11.8 for nongravity cantilever walls.

Procedures for calculating nominal structural resistance for concrete and steel components are provided in Sections 5 and 6.

15.9.6—Loading

The provisions of Section 3, as modified by Article 15.8, shall apply.

15.9.7—Movement at the Service Limit State

The provisions of Articles 10.6.2, 10.7.2, 10.8.2, or 11.8.3, as appropriate, shall apply.

15.9.8—Safety against Geotechnical Failure at the Strength Limit State

Spread footings or footings supported on two or more rows of driven piles or drilled shafts shall be designed in accordance with the provisions of Articles 10.6.3, 10.7.3, or 10.8.3, respectively.

Footings supported on a single row of driven piles or drilled shafts or on a continuous embedded foundation wall ("trench footing") shall be designed in accordance with the provisions of Article 11.8.4 using the earth pressure diagrams provided in Article 3.11.5.10.

For overall stability, the provisions of Article 11.6.3.7 shall apply.

15.9.9—Seismic Design

The effect of earthquake loading shall be investigated using the Extreme Event I limit state of Table 3.4.1-1 with load factor $\gamma_p = 1.0$, and an accepted methodology.

15.9.10—Corrosion Protection

The provisions of Article 11.8.7 shall apply.

15.9.11—Drainage

Where sound barriers support earth loads or can impede water flow, the provisions of Article 11.8.8 shall apply.
